osmotic solutes, such as glycine betaine and others, to balance the cytoplasm osmotically with the surrounding medium, the anaerobic halophilic Bacteria do not (Oren, 1986b; Oren et al., 1997; Rengpipat et al., 1988b). High concentrations of Na^+, K^+ and Cl^- were measured inside the cells of *Haloanaerobium praevalens*, *Halobacteroides halobius* (Oren, 1986b) and *Haloanaerobium acetoethylicum* (Rengpipat et al., 1988b), high enough to be at least isotonic with the medium. The intracellular ionic concentrations of individual cells of *Haloanaerobium praevalens* were assayed by means of X-ray microanalysis with the transmission electron microscope. Apparent intracellular cation concentrations between 1.22 and 1.91 M and chloride concentrations of 0.93–1.57 M were measured in cells growing exponentially in 2.6 M total salts. Because the cells flatten during sample preparation, these values probably underestimate the true intracellular concentrations. In exponentially growing cells, K^+ was the major cation (70% of the cation sum). Stationary phase cells showed a high variability among individual cells, part of the cells containing high concentrations of NaCl rather than KCl (Oren et al., 1997).

In accordance with the high intracellular salt concentrations, the intracellular enzymatic machinery should be adapted to function in the presence of high salt. Indeed, those enzymes tested (glyceraldehyde-3-phosphate dehydrogenase, NAD-linked alcohol dehydrogenase, pyruvate dehydrogenase, and methyl viologen-linked hydrogenase from *Haloanaerobium acetoethylicum*; hydrogenase and CO dehydrogenase activities of *Acetohalobium arabaticum*; and the fatty acid synthetase complex of *Haloanaerobium praevalens*) generally function better in the presence of molar concentrations of salts than in the absence of salts, and they can be expected to be fully active at the actual salt concentrations present in the cytoplasm (Oren and Gurevich, 1993; Rengpipat et al., 1988b; Zavarzin et al., 1994). Also similar to the aerobic halophilic Archaea, the tested members of the Haloanaerobiales have highly acidic bulk cellular protein (Oren, 1986b). However, no especially high content of acidic amino acids was found in the ribosomal A-protein of *Haloanaerobium praevalens* (Matheson et al., 1987).

Several strains (*Haloanaerobium saccharolyticum*, *Halobacteroides halobius*, *Halobacteroides elegans*, *Haloanaerobacter lacunaris*) can use methanethiol as the sole source of assimilatory sulfur for growth (Kevbrin and Zavarzin, 1992a; Zhilina et al., 1997). An interesting feature common at least to several members of the Haloanaerobiales is the ability to use oxidized sulfur compounds as electron acceptors or electron sinks. Thus, *Haloanaerobium congolense* uses thiosulfate and elemental sulfur as electron acceptors. Thiosulfate improved carbohydrate utilization and enhanced growth rates. Addition of thiosulfate or sulfur increased the growth yield 6-fold and 3-fold, respectively. In addition, the presence of thiosulfate alleviated growth inhibition by accumulating hydrogen (Ravot et al., 1997). Also, reduction of elemental sulfur to sulfide was reported in *Haloanaerobium saccharolyticum* (Zhilina et al., 1992b), in *Haloanaerobacter lacunaris* (Zhilina et al., 1992a), and in *Halobacteroides elegans* (Kevbrin and Zavarzin, 1992a; Zhilina et al., 1997). Moreover, thiosulfate reduction was observed in *Orenia marismortui* (Oren et al., 1987). *Acetohalobium arabaticum* was reported to slowly reduce sulfur to sulfide, but this was not accompanied by growth enhancement (Kevbrin and Zavarzin, 1992b; Zavarzin et al., 1994). Other compounds that can serve as electron sinks are nitro-substituted aromatic compounds such as nitrobenzene, nitrophenols, 2,4-dinitrophenol and 2,4-dinitroaniline, found to be reduced by *Haloanaerobium praevalens* and by *Orenia marismortui* (Oren et al., 1991, 1992).

Certain members of the Haloanaerobiales grow at high temperatures (*Halothermothrix orenii*) or at high pH (*Natroniella acetigena*, *Haloanaerobium alcaliphilum*). Little is known about the special adaptations of these bacteria that enable them to withstand both the salt stress and the additional stress caused by the high temperature or pH.

Ecology

Halophilic anaerobic Bacteria of the order Haloanaerobiales may be found in any hypersaline anaerobic environment in which simple organic compounds such as sugars and amino acids are available. They therefore abound in the anaerobic sediments of hypersaline lakes and saltern evaporation ponds, and they also appear to be widespread in anaerobic brines associated with oil deposits.

For the saccharolytic representatives, the ability to use substrates such as glycerol, glucosylglycerol, trehalose, cellulose and chitin may be of particular ecological importance. The first three compounds are accumulated at high concentrations as organic osmotic solutes by aerobic photosynthetic halophilic microorganisms inhabiting salt lakes (glycerol in the green unicellular alga *Dunaliella*, glucosylglycerol and trehalose in a variety of cyanobacteria). Thus, such compounds can be expected to be available to the anaerobic bacterial community in the bottom sediments of these lakes. *Haloanaerobium saccharolyticum* (both subsp. *saccharolyticum* and

subsp. *senegalense*) ferments glycerol (Cayol et al., 1994a; Zhilina et al., 1992b), and so does *Haloanaerobium lacusrosei* (Cayol et al., 1995). No details have been published on the fermentation products made when glycerol serves as energy source. Glycerol oxidation by anaerobic halophiles was reported to be markedly improved through interspecies hydrogen transfer when the glycerol fermenters were grown in coculture with H_2-consuming sulfate-reducing bacteria (Cayol et al., 1995). *Haloanaerobium saccharolyticum* was isolated from a cyanobacterial mat, dominated by *Microcoleus chthonoplastes* and covering the bottom of a hypersaline lagoon in the Crimea; its ability to use glucosylglycerol, the osmotic solute produced by *Microcoleus* and many other cyanobacteria, may be of great ecological importance (Zhilina and Zavarzin, 1991). The same organism also degrades trehalose, produced by other cyanobacteria for similar purposes (Zhilina et al., 1992b). The hypersaline lagoons of the Crimea also contain large masses of dead macroalgae (*Cladophora*). Such environments show high cellulolytic activity; the optimum salt concentration for cellulose decomposition was 15%, and decomposition was possible up to 25% salt. During cellulose decomposition, a transient accumulation of reducing sugars was observed in the medium (Simankova and Zavarzin, 1992). A cellulose-degrading halophilic anaerobe, *Halocella cellulolytica*, was isolated from this habitat (Simankova et al., 1993), and its cellulase complex was characterized in part (Bolobova et al., 1992). Another biopolymer that may be available in large quantities in hypersaline lakes is chitin, derived from the brine shrimp *Artemia* and from larvae of the brine fly, which are often abundant in such environments. Evolution of gas bubbles was observed from the sediment of a California saltern containing massive amounts of dead brine shrimp. Two strains of *Haloanaerobacter chitinovorans* were isolated from this saltern, of which only one grew on chitin. This strain was characterized by the presence of two chitin-induced extracellular proteins of 38 and 40 kDa molecular mass (Liaw and Mah, 1992). Another substrate that may be available abundantly in hypersaline environments is glycine betaine. This compound is produced as an osmotic solute by the most halophilic among the cyanobacteria and by halophilic anoxygenic photosynthetic bacteria such as *Halorhodospira* species. Glycine betaine was found to be fermented to acetate and trimethylamine by Haloanaerobium alcaliphilum isolated from the Great Salt Lake, Utah (Tsai et al., 1995), and by the (non-saccharolytic) *Acetohalobium arabaticum*. The latter species produces only minor amounts of trimethylamine, as most is converted to acetate (Zhilina and Zavar-

zin, 1990b). Glycine betaine can also be used as an electron acceptor in the Stickland reaction by *Haloanaerobacter salinarius* and *Haloanaerobacter chitinovorans*, with H_2 or serine as electron acceptor (Mouné et al., 1999).

Typical fermentation products of the saccharolytic representatives of the Haloanaerobiales are acetate, ethanol, hydrogen, and CO_2 (see Tables 2–3). The homoacetogenic *Acetohalobium arabaticum* can use hydrogen to reduce CO_2 for the production of additional acetate in a chemolithotrophic mode of life. Little is known on the fate of the other end products of the fermentation processes performed by the halophilic anaerobes in their natural habitats. The methylated amines formed during degradation of glycine betaine are excellent substrates for the growth of halophilic methanogenic bacteria (Zhilina and Zavarzin, 1990a) or for acetate production by *Acetohalobium arabaticum* (Zhilina and Zavarzin, 1990a, 1990b). No sulfate-reducing bacteria have been isolated as yet that grow at salt concentrations exceeding 20%, and no moderately or extremely halophilic methanogens are known that utilize hydrogen or acetate as energy sources. Acetate was suggested to be a dead-end product in the anaerobic halophilic community (Zhilina and Zavarzin, 1990a).

Halophilic anaerobic bacteria of the order Haloanaerobiales also have been found in environments, which in addition to the osmotic stress are characterized by extremes of temperature or pH. Thus, *Halothermothrix orenii*, the first truly thermophilic halophilic anaerobe, was isolated from Chott El Guettar, a warm saline lake in Tunisia. It grows optimally at 60°C, and up to 68°C at salt concentrations as high as 20%. As expected on the basis of its high temperature optimum, the isolate has unusual lipids, with branched-chain fatty acids (iso-15:0, anteiso-15:0, iso-17:0) accounting for about 75% of the fatty acids (Cayol et al., 1994b). An *Acetohalobium arabaticum* strain designated Z-7492, showing 78% DNA-DNA homology with the type strain, had a temperature optimum of 55°C (Kevbrin et al., 1995). Several halophilic anaerobes can grow at high pH values. *Haloanaerobium praevalens* from the Great Salt Lake was described as a moderate alkaliphile (Zeikus et al., 1983). *Haloanaerobium alcaliphilum*, isolated from the same environment, has a broad pH range (5.8–10) (Tsai et al., 1995). The alkaline (pH 10.2) Lake Magadi, Kenya, was shown to harbor a varied anaerobic community, including cellulolytic, proteolytic, saccharolytic, and homoacetogenic bacteria (Zhilina and Zavarzin, 1994). The homoacetogen *Natroniella acetigena* was isolated from this environment. This organism can grow on lactate, ethanol, pyruvate, glutamate, and propanol, forming acetate as the

main end product, and excreting propionate when grown on propanol. In contrast to *Acetohalobium arabaticum*, it is unable to grow autotrophically on hydrogen + carbon dioxide. Its pH optimum is 9.8–10.0, and growth has been observed up to pH 10.7 (Zhilina et al., 1996).

Quantitative data on the occurrence of members of the Halobacteriales in hypersaline anoxic environments are scarce. *Haloanaerobium praevalens* was reported to be present in Great Salt Lake surface sediment in numbers of up to 10^8 per ml sediment (Zeikus, 1983; Zeikus et al., 1983), where 10^3–10^5 *Halobacteroides halobius* cells were counted per ml of Dead Sea sediment (Oren et al., 1984b). Up to 10^7–10^9 anaerobic halophilic cellulolytic bacteria were enumerated per ml sediment in lagoons of the Arabat strait (Simankova and Zavarzin, 1992). Up to 4.6×10^3 anaerobic halophiles were counted in anaerobic brines associated with an oil reservoir in Oklahoma (Bhupathiraju et al., 1991, 1993). The few data available prove that these anaerobic halophiles may form a significant component of the ecosystem in anaerobic hypersaline sediments.

A search for novel organisms, both by using a wider variety of potential substrates and salt concentrations in enrichment cultures or in media for direct isolation and by extending the search to previously unexplored habitats, will undoubtedly yield a much greater variety of anaerobic fermentative bacteria than presently known.

Applications

The Haloanaerobiales have found few applications thus far. It has been suggested that they may be useful in microbially enhanced oil recovery from oil reservoirs by plugging of porous reservoirs and useful for producing commodities, such as gases, biosurfactants, polymers, etc., by anaerobically metabolizing nutrients in ambient environmental conditions (Bhupathiraju et al., 1991).

The use of anaerobic halophilic bacteria in the industrial fermentation of complex organic matter has been proposed, and preliminary tests have been made (Wise, 1987), but to my knowledge possible applications of the organisms in such processes are still in an experimental stage.

CHAPTER 1.2.28

The Genus *Eubacterium* and Related Genera

WILLIAM G. WADE

Phylogeny

The genus *Eubacterium*, because of its loose definition (see Taxonomy section below), includes species with a diverse range of phenotypes. Not surprisingly, therefore, 16S rRNA gene sequence comparison has revealed that the species of this genus are widely distributed within the phylogenetic tree. At present, 16S rRNA sequences have been determined for 45 of the 46 species and subspecies. These all fall within the phylum Firmicutes (Fig. 1). The type species, *Eubacterium limosum* belongs to a cluster with *Eubacterium callanderi* and *Eubacterium barkeri*, and it has been suggested that the genus *Eubacterium* sensu stricto should be restricted to these species (Willems and Collins, 1996), with the possible addition of *Eubacterium aggregans*, which also belongs to this phylogenetic group. Other major clusters of *Eubacterium* species within the Firmicutes include one consisting of *Eubacterium biforme*, *Eubacterium cylindroides*, *Eubacterium dolichum* and *Eubacterium tortuosum* within the family Erysipelotrichaceae, and a group of asaccharolytic species isolated from the oral cavity including *Eubacterium brachy*, *Eubacterium infirmum*, *Eubacterium minutum*, *Eubacterium nodatum*, *Eubacterium saphenum* and *Eubacterium sulci*, which are related to *Mogibacterium* (formerly *Eubacterium*) *timidum*. Other *Eubacterium* species are scattered among the Firmicutes and frequently have *Clostridium* species as close relatives. This is another heterogeneous genus of Gram-positive anaerobes; spore formation is the principal characteristic by which strains are placed within *Clostridium* rather than *Eubacterium*. The intermingling of species of these two genera throughout the phylogenetic tree suggests either that sporulation has emerged frequently throughout evolution or that it is a feature that has been lost from some species over time.

Other species recently transferred from *Eubacterium* such as *Eggerthella lenta* (Wade et al., 1999), *Collinsella aerofaciens* (Kageyama et al., 1999a), *Atopobium fossor* (Kageyama et al., 1999b), *Slackia exigua* (Wade et al., 1999) and the recently described genera *Cryptobacterium*

(Nakazawa et al., 1999) and *Olsenella* (Dewhirst et al., 2001) are found in the phylum Actinobacteria (Fig. 2), a phylum of Gram-positive organisms with DNA of mainly high G+C content.

Taxonomy

The genus definition for *Eubacterium* is rather unsatisfactory as it is defined by default; it includes those Gram-positive, nonsporeforming, obligately anaerobic rods that do not produce: 1) propionic acid as major acid (in contrast to *Propionibacterium*); 2) lactic acid alone (in contrast to *Lactobacillus*); 3) more acetic acid than lactic acid with and without formic acid (in contrast to *Bifidobacterium*); and 4) succinic acid (in the presence of carbon dioxide) and lactic acid with small amounts of acetic or formic acid (in contrast to *Actinomyces*; Moore and Holdeman Moore, 1986). Because of this loose definition, the genus is highly heterogeneous. The DNA G+C content of the current *Eubacterium* species is 30–57 mol%. As mentioned above, many of the species recently transferred to other existing or novel genera belong to the *Actinobacteria* and typically have high DNA G+C content, e.g., 62% for *E. lenta* and 60–64 % for *S. exigua*.

The majority of current species, therefore, do not belong in the genus *Eubacterium* sensu stricto and will be moved to other existing or novel genera in time. This process is under way and a number of species have been transferred already. In addition to those mentioned above, *E. formicigenerans* has been moved to the novel genus *Dorea* (Taras et al., 2002) and *E. timidum* is the type species of the new genus *Mogibacterium* (Nakazawa et al., 2000). *Eubacterium suis* has moved twice: first to *Actinomyces* (Ludwig et al., 1992) and then to *Actinobaculum* (Lawson et al., 1997).

Given the phylogenetic association between the genera *Eubacterium* and *Clostridium*, it is not surprising that many phenotypic features are shared. For example, most of the saccharolytic species of *Eubacterium* described form butyric acid and hydrogen gas, as do many saccharolytic
Fig. 1. Phylogenetic tree based on 16S rRNA gene sequence comparisons showing *Eubacterium* species and related taxa within the phylum Firmicutes.
Fig. 2. Phylogenetic tree based on 16S rRNA gene sequence comparisons showing *Eubacterium* species and related taxa within the phylum Actinobacteria.

Clostridium species. In addition to ethanol, butanol is formed by *E. saburreum* and *E. tenue*, as also seen in some solvent-producing clostridia (Bahl and Gottschalk, 1988). Caproic acid is generally quite seldom encountered as end product but can be a unique product of *Pseudoramibacter* (*Eubacterium*) *alactolyticus*, *E. biforme*, *E. limosum* and *E. pyruvativorans*, as well as of *Clostridium kluyveri*, *Peptococcus niger* and *Megasphaera elsdenii* (Holdeman et al., 1977; Moore and Holdeman Moore, 1986). Some *Eubacterium* spp. have the ability to degrade amino acids, as shown by the identification of isobutyric and isovaleric acids as products of *E. acidaminophilum*, *E. brachy*, *E. callanderi*, *E. combesii*, *E. limosum* and *E. tenue* (Moore and Holdeman-Moore, 1986; Mountfort et al., 1988; Zindel et al., 1988), and of phenylacetic acid as a product of *M. timidum* (Hill et al., 1987). As observed for clostridia (Andreesen et al., 1989), specialists able to degrade purines (*E. angustum*), trihydroxybenzenoids (*E. oxidoreducens*), O-methoxylated aromatic acids (*E. callanderi*) or steroids (*E. desmolans*) have also been isolated (Beuscher and Andreesen, 1984; Krumholz and Bryant, 1986; Morris et al., 1986; Mountfort et al., 1988). Cholesterol reduction is a particular feature of *E. coprostanoligenes* (Freier et al., 1994). Autotrophic growth on H_2 plus CO_2 or on one-

carbon compounds such as CO, formate and methanol is also possible in *E. limosum* (Genthner et al., 1981; Genthner and Bryant, 1982; Genthner and Bryant, 1987).

Some *Eubacterium* species (for instance *E. plautii*) are either Gram-negative (Hofstad and Aasjord, 1982) with very occasional weak Gram-positive areas in the cells or they decolorize rather easily e.g., *E. cylindroides*. The ambiguity of this fundamental character has caused considerable confusion, for example, *Eubacterium sulci* was originally considered to be Gram-negative and as such was originally described as a member of the genus *Fusobacterium* (Cato et al., 1985; Jalava and Eerola, 1999). Therefore, these species can only be classified with certainty by demonstrating the absence of lipopolysaccharides, especially of 3-hydroxy fatty acids, and by analysis of the outer membrane proteins (Baardsen et al., 1988). The chemical composition of the peptidoglycan has been proven to be a useful taxonomic marker since members of this group display a wide variety of types, such as the *meso*-diaminopimelic acid-direct type (Alγ according to the nomenclature of Schleifer and Kandler, 1972) in *E. acidaminophilum*, *E. angustum*, *E. alactolyticum*, *E. saburreum* and *E. tenue*; the LL-diaminopimelic acid-glycine type (A3γ) in *E. combesii* and *E. lenta*; various unique structures in *E. nodatum* and *A. suis*; and the B2α type (found in *E. limosum* and *E. callanderi*) where peptide bridges are connected to the D-glutamic acid residue (Tanner et al., 1981; Weiss, 1981; Wegienek and Reddy, 1982; Beuscher and Andreesen, 1984; Zindel et al., 1988; Severin et al., 1989a; Severin et al., 1989b). *Holdemania filiformis*, phylogenetically related to the genus *Erysipelothrix*, resembles it in having type B cell wall murein. Indeed, further analysis revealed the murein to be of a type previously undescribed: B1δ(l-Ala)-D-Glu-Gly-L-Lys (Willems et al., 1997). Whether the related species *Bulleidia extructa* and *Solobacterium moorei* possess a similarly unusual murein composition remains to be determined.

Habitat

Eubacterium species are found in the mammalian mouth and intestinal tract (including the rumen) and in the environment (Table 1).

In quantitative studies of the human intestinal flora, *Eubacterium* species were found to be the second most numerous genus with a median count of about 6×10^{10} organisms per g of dry weight of feces compared with 10^{11} cells per g of *Bacteroides* species (Finegold et al., 1983). *Eubacterium* species were recovered from 94% of subjects and *C. aerofaciens*, *E. contortum*, *E.*

cylindroides, *E. lenta* and *E. rectale* were identified in at least 20% of the cases, demonstrating these to be the predominant *Eubacterium* spp. in that habitat. *Collinsella aerofaciens* was present in 40–60% of the cases, independent of the diet or state of health, whereas the presence of other species varied from three- to sixfold. Subsequent studies of the intestinal flora have resulted in the description of many new species, including *E. dolichum*, *E. eligens*, *E. formicigenerans*, *E. hadrum*, *E. hallii*, *E. ramulus* and *E. siraeum* (Holdeman and Moore, 1974; Holdeman et al., 1976; Moore et al., 1976). *Eubacterium ramulus* is of particular interest as it is capable of degrading a wide range of flavonoids, compounds obtained from food and thought to be beneficial to health (Simmering et al., 1999). Schwiertz et al. (2000) used oligonucleotide probes to detect ten *Eubacterium* species in human fecal samples. *Eubacterium biforme*, *E. cylindroides*, *E. hadrum*, *E. ventriosum* and *E. lenta* were detected, and overall the results were similar to those previously seen in cultural studies.

The majority of *Eubacterium* species found in the human mouth are asaccharolytic and mainly found in oral disease. The predominant species are *E. brachy*, *E. nodatum*, *E. saphenum*, *M. timidum* and *S. exigua* (Holdeman et al., 1980; Uematsu and Hoshino, 1992; Uematsu et al., 1993; Poco et al., 1996). Some saccharolytic species are found, and these include *E. saburreum*, *E. yurii*, *B. extructa* and *S. satelles*. *Eubacterium yurii* forms interesting cellular arrangements; all three subspecies form three-dimensional "test tube brush" arrangements from "*Actinomyces*-like" granules, which are perpendicular to a central stalk (Margaret and Krywolap, 1986; Margaret and Krywolap, 1988).

Many of the species found in the environment are also found in infectious material. This suggests that *Eubacterium* species naturally occurring in soil, for example, can act as opportunist pathogens in man.

Some species appear to be associated with specific host organisms. For example, *E. tarantellae* has been isolated from infected fish brains (Udey et al., 1977), *Atopobium fossor* from the pharynx and tooth abscesses of horses (Bailey et al., 1986), and *E. plautii* as an endosymbiont of *Entamoeba histolytica* (Hofstad and Aasjord, 1982).

The rumen is an ideal habitat for *Eubacterium* species because of its rich supply of organic materials (Stewart and Bryant, 1988). *Eubacterium ruminantium* seems to be well adapted to these conditions for it shows a requirement for sodium and rumen fluid and constitutes about 3–7% of the total isolates using a nonspecific medium (Bryant, 1959). *Eubacterum limosum* is one of the nutritionally most versatile species, degrading carbohydrates, amino acids, lactate and methanol, and even growing autotrophically on $H_2 + CO_2$ or CO (Genthner et al., 1981; Genthner and Bryant, 1982). Strains of *E. limosum* have been isolated from the rumen fluid of sheep but not of a steer. The fiber-degrading species *E. cellulosolvens*, *E. uniforme* and *E. xylanophilum* can be specifically enriched using cellulose, cellobiose or xylan as the selective substrate (Van Gylswyk and Van der Toorn, 1985; Van Gylswyk and Van der Toorn, 1986). Xylan utilizers represent about 6% of the total viable count, with *E. uniforme* as the more versatile organism present (at about 5%) and *E. xylanophilum* as a specialist for cellobiose and xylan (at about 1%) of the xylan-degrading flora (Van Gylswyk and Van der Toorn, 1985). Lignins, tannins and flavonoids have trihydroxybenzenoids, so that trihydroxybenzenoids are common constituents of the rumen diet. *Eubacterium oxidoreducens* degrades gallate, pyrogallol, phloroglucinol and quercetin in the presence of formate or hydrogen as electron donors; crotonate can be degraded without an exogenous electron donor. *Eubacterium* oxidoreducens cannot grow on conventional media in the absence of one of these substrates (Krumholz and Bryant, 1986). A pathway for gallate and phloroglucinol degradation to acetate and butyrate has been proposed (Krumholz et al., 1987), and the enzymes catalyzing unique reactions, like pyrogallol-phloroglucinol isomerase and phloroglucinol reductase, have been characterized (Krumholz and Bryant, 1988; Haddock and Ferry, 1989). *Eubacterium pyruvativorans* is found in the sheep rumen and does not ferment sugars but can grow on pyruvate or trypticase, forming caproate as the major endproduct (Wallace et al., 2003).

Man-made environments for the treatment of waste of various sorts have also been shown to be habitats capable of supporting the growth of *Eubacterium* species. *Eubacterium limosum* and *E. callanderi* have been isolated from the anaerobic digesters of sewage plants (Genthner et al., 1981; Mountfort et al., 1988). *Eubacterium callanderi* is somewhat specialized for the cleavage of phenylether bonds present in O-methoxylated aromatic substrates such as ferulate, sinapate, syringate, vanillate or 3,4,5-trimethoxycinnamate (Mountfort et al., 1988). *Eubacterium angustum*, isolated from sewage sludge, has a restricted substrate range, utilizing only few purine compounds like uric acid, xanthine, guanine and hypoxanthine (Beuscher and Andreesen, 1984). Purines form a major fraction of the cell constituents and are excreted as N-rich compounds by birds, reptiles, insects and other animals (Vogels and Van der Drift, 1976). *Eubacterium acidaminophilum* is another nutritionally modest organism isolated from sludge, utilizing in pure culture only glycine and serine

as single substrates. However, its substrate spectrum is extended to other amino acids or to some organic acids if a hydrogen-accepting organism or an acceptor like betaine, creatine or sarcosine is also present (Zindel et al., 1988; Hormann and Andreesen, 1989). *Eubacterium coprostanoligenes*, isolated from a hog sewage lagoon, reduces cholesterol to coprostanol but does not require it for growth, although lecithin is needed (Freier et al., 1994). *Eubacterium aggregans* was isolated from a particularly specialized site: an anaerobic digestor fed with wastewater from an olive mill (Mechichi et al., 1998).

Isolation

For the majority of species, the complex media recommended for anaerobes by the Anaerobe Laboratory of the Virginia Polytechnic Institute (Holdeman et al., 1977) and the Wadsworth-KTL Anaerobe Laboratory Manual (Jousimies-Somer et al., 2002) are adequate for growth. However, because of the still-unresolved nutritional requirements of some species of *Eubacterium*, these media have to be supplemented with complex ingredients (vitamins, rumen fluid, volatile fatty acids, and substrates specific to the species) to obtain reasonable growth. Although these rich media appear to contain all necessary nutrients, growth of some species is still poor (Hill et al., 1987). To enhance growth of *E. acidaminophilum*, for example, selenium as a special micronutrient and a hydrogen acceptor or donor must be present (Zindel et al., 1988). If these are present in a balanced ratio, good growth will even occur in a simple defined medium. A salt solution (containing $CaCl_2$, $MgCl_2$, potassium phosphate, $NaHCO_3$ and NaCl; Holdeman et al., 1977) is a constituent of most media used to cultivate *Eubacterium* species. However, some species are inhibited by phosphate concentrations higher than 5 mM where the pH-buffering capacity is quite low (Zindel et al., 1988).

Most of the *Eubacterium* species are highly sensitive towards oxygen. Only *E. desmolans* can tolerate 4 h of exposure to atmospheric air (Morris et al., 1986). Nitrate reduction is a property quite seldom encountered within the genus *Eubacterium*, especially as a marker valid for all strains (Bokkenheuser et al., 1979; Moore and Holdeman-Moore, 1986). This might indicate that most of the species within the genus are true anaerobes.

Identification

The species described in this chapter are difficult to identify. Many are slow-growing, have fastidi-

ous nutritional requirements, and are unreactive in the commonly used biochemical and physiological tests. For these reasons, particular caution should be exercised using commercially available rapid identification kits. The indifferent growth of many *Eubacterium* species can make the constituent tests in these kits especially unreliable and furthermore the preponderance of negative reactions makes interpretation of the test results difficult. If identification by phenotypic means is attempted, the test methods described by Holdeman et al. (1977) are recommended. As mentioned before, the assignment of an organism to the genus *Eubacterium* depends on the nature of its metabolic products, their ratio on certain standard media, and on the pH decrease observed during the fermentation of carbohydrates to the respective acids (Moore and Holdeman-Moore, 1986). Fermentation tests should be performed with pre-reduced anaerobically sterilized sugars as long as growth in the basal medium is adequate. Only by using identical, well-specified conditions, can the species be differentiated by identification keys and tables (Moore and Holdeman-Moore, 1986). Production (or absence) of butyric acid and acid formation leading to a sharp pH drop (or none) are the main lines of differentiation. Selected characteristics used for preliminary identification of *Eubacterium* and related species are given in Table 2. Certain species of *Eubacterium* cannot be definitively differentiated; for instance, *E. budayi* and *E. nitritogenes* are very closely related in their phenotypes. Furthermore, if *Eubacterium* spp. also hydrolyze gelatin, they could be mistaken for *Clostridium perfringens*, a situation that might also obtain for *E. moniliforme* and *E. ventriosum* (Moore and Holdeman-Moore, 1986).

Increasingly, 16S rRNA sequence analysis is becoming the method of choice for bacterial identification, and this method works well for this group. The 16S rRNA sequences of the majority of *Eubacterium* species show sufficient sequence divergence from their close neighbors for identification to be possible, with a partial sequence of around 500 base pairs. An exception however is the genus *Mogibacterium*, where the species *M. diversum* and *M. neglectum* cannot be easily distinguished from *M. vescum* by 16S rRNA analysis (Nakazawa et al., 2002).

The use of 16S rRNA gene sequence analysis for identification of clinical isolates provisionally identified as "*Eubacterium*" has revealed that a significant proportion do not correspond to named species (Downes et al., 2001; Munson et al., 2002). Although progress is being made in the proposal of new genera and species to accommodate these strains, much remains to be done and it can be expected that numerous novel taxa

belonging to this group will be described in the years to come.

Disease

The genus *Eubacterium* was proposed by Prévot (1938) to describe a group of bacteria isolated from human feces that were considered to be beneficial. Although no *Eubacterium* species have been shown to be capable of causing infections alone, a number of species are isolated from infections (Table 1), with the primary source of the infecting organisms thought to be the lower gut. *Eubacterium lenta* is the species most frequently isolated.

Some species have been implicated as key players in the multispecies biofilms associated with infections in the mouth. For example, Uematsu and Hoshino (1992) showed that *Eubacterium* constituted 54% of the microflora in periodontal pockets, and Moore et al. (Moore et al., 1982; Moore et al., 1983) showed that *E. brachy*, *E. nodatum*, *M. timidum* and *S. exigua* were associated with periodontally diseased sites. Serum antibodies to these organisms were found in periodontal patients compared to controls, providing further evidence of their active involvement in the disease process (Tew et al., 1985; Gunsolley et al., 1990; Smith and Wade, 1999). *Eubacterium* species are also frequently isolated from other oral infections including dental caries (Hoshino, 1985) and endodontic (Munson et al., 2002) and dentoalveolar infections (Wade et al., 1993).

Eubacterium species of oral origin have also been reported to cause opportunistic infections at a variety of other body sites (Allen, 1985; Hill et al., 1987; Finegold and George, 1989). Reports of other *Eubacterium* species causing human disease include *E. plautii* causing a fulminant infection following a dog bite (Garre et al., 1991) and a case of bacteremia caused by *E. callanderi* (Thiolas et al., 2003). *Collinsella aerofaciens* has been implicated in rheumatoid arthritis (Eerola et al., 1994) and the particular chemical composition of its cell wall peptidoglycan appears to be responsible for its arthritogenicity (Zhang et al., 2001).

Applications

As emphasized above, species of *Eubacterium* and related genera, especially *E. lenta*, represent a dominant group of organisms in the human gut. Although this species is normally inactive in most biochemical tests, organisms phenotypically related to it can catalyze a wide variety of transformation reactions on steroids (Bokken-

heuser et al., 1979; MacDonald et al., 1983; Edenharder and Mielek, 1984; Hylemon, 1985; Akao et al., 1988) or are able to split off the side chain of cortisol, as is characteristic for *E. desmolans* (Bokkenheuser et al., 1986; Morris et al., 1986). So far, biotransformations of steroids carried out by anaerobes have not received any industrial attention (Sedlaczek, 1988), although the inability of these organisms to cleave the ring system of steroids might be regarded as an advantage.

Some *Eubacterium* species can reduce cholesterol to coprostanol. Most of these isolates require the presence of alkenyl ether lipids (plasmalogens) as a specific growth factor (Mott and Brinkley, 1979). *Eubacterium coprostanoligenes* reduces cholesterol via the formation of 4-cholesten-3-one, which is then reduced to coprostanol with coprastanone as an intermediate (Ren et al., 1996). The possibility of using this organism in a probiotic way to reduce blood cholesterol levels has been investigated in hens and mice, but the results to date have been equivocal (Li et al., 1996; Li et al., 1998).

Cortisol desmolase and 20-β-hydroxysteroid dehydrogenase are unique for *E. desmolans* (Bokkenheuser et al., 1986; Morris et al., 1986). A 21-dehydroxylating activity leading from 11-deoxycorticosterone (21-hydroxy-4-pregnene-3, 20-dione) to progesterone is known for *E. lenta* (Bokkenheuser et al., 1977). This species can also produce a 16 α-dehydroxylase (Bokkenheuser and Winter, 1980), a 12 α- or 12 β-hydroxysteroid dehydrogenase (MacDonald et al., 1983), and bile acid 3 α-, 3 β-, 7 α-, and 12 α-hydroxysteroid dehydrogenase (Edenharder and Mielek, 1984), and forms ω-muricholic acid from the β-derivative (Eyssen et al., 1983). Epimerization reactions occur via the corresponding keto-compounds and might require the cometabolism of two species (MacDonald and Hutchinson, 1982; Edenharder and Schneider, 1985; Canzi et al., 1989).

The 7-dehydroxylase activity of *Eubacterium* sp. VPI 12 708 (closely related to *E. lenta*) seems to form a novel bile acid nucleotide to labilize the 7-hydroxy group to generate a 3-keto-Δ4,6-steroid nucleotide intermediate (Coleman et al., 1987). Proteins and even genes involved in the 7-dehydroxylation reaction have been characterized (Coleman et al., 1987; White et al., 1988a). A multigene family seems to be involved, and a 27-kDa protein exhibits extensive sequence homologies to alcohol and polyol dehydrogenases (White et al., 1988b).

The activity of the enzyme 16-hydroxyprogesterone dehydroxylase in combination with a 16-dehydroxyprogesterone reductase and progesterone reductase to form finally 17-isopregnanedione are 10-fold higher if H_2 or pyruvate is

present (Glass and Burley, 1985). A study of many strains similar to *E. lenta* demonstrated that a few strains were also able to deconjugate both glycine and taurine conjugates of cholic acid and chenodeoxycholic acid. All strains studied could reduce one double bond of linoleic acid to *trans*-vaccenic acid (Eyssen and Verhulst, 1984). The reduction of the unsaturated lactone ring of digoxin, a cardiac glycoside, results in the formation of 99% pure 20R-dihydrodigoxin without hydrolysis of the glycosidic bond by *E. lenta* (Robertson et al., 1986). Also, the digitoxin derivatives are selectively reduced to the 20R-form during active growth (Chandrasekaran et al., 1987). Thus, many stereoselective biotransformation reactions can be performed by a variety of strains of *E. lenta*.

Eubacterium limosum is the other species that is of interest to biotechnologists because of its production of cobamides (Perlman and Semar, 1963; Vogt et al., 1988) and carboxylic acids (Bryant and Genthner, 1983; Lindley et al., 1987). The organism is a part of several highly efficient methanogenic consortia, because of its high metabolic versatility (Zellner and Winter, 1987).

CHAPTER 1.2.29

The Genus *Mycoplasma* and Related Genera (Class Mollicutes)

SHMUEL RAZIN

Introduction

Mycoplasmas are distinguished phenotypically from other bacteria by their minute size and total lack of a cell wall. Taxonomically, the lack of cell walls is used to separate mycoplasmas from other bacteria and to place them in a class named "Mollicutes" (*mollis*, soft; *cutis*, skin, in Latin). The classification of Mollicutes and the properties distinguishing the established taxa are presented in Table 1. Though the trivial terms mycoplasmas or mollicutes have been used interchangeably to denote any species included in Mollicutes, the trivial names "ureaplasmas," "entomoplasmas," "mesoplasmas," "spiroplasmas," "acholeplasmas," "asteroleplasmas," and "anaeroplasmas" are routinely used for members of the corresponding genus. Molecular characterization of the uncultured plant and insect mycoplasma-like organisms (MLOs) has provided strong experimental support for their inclusion in the class Mollicutes (see the section Phylogeny and Taxonomy). Consequently, the trivial term "phytoplasmas" has been proposed to replace the awkward name "mycoplasma-like organisms." About 200 established species have already been described within the class Mollicutes, and this number continues to rise, including the still uncultured mollicutes, such as the phytoplasmas and the hemotrophic parasites *Haemobartonella* and *Eperythrozoon* species, recently identified as mollicutes and given the trivial name "hemoplasmas" (Neimark et al. 2001).

The interested reader is referred to a number of books on various aspects of mycoplasmology published during the last decade or so (Maniloff et al., 1992; Rottem and Kahane, 1993; Razin and Tully, 1995; Tully and Razin, 1996; Miles and Nicholas, 1998). The most recent multi-authored treatise covering the molecular biology and pathogenicity of mycoplasmas has been published in the summer of 2002 (Razin and Herrmann, 2002). Several recent general reviews on the molecular biology, genetics and pathogenicity of mycoplasmas are also available (Dybvig and Voelker, 1996; Baseman and Tully, 1997; Razin et al., 1998).

Morphology

The total lack of a cell wall explains many of the unique properties of the mycoplasmas, such as sensitivity to osmotic shock and detergents, resistance to penicillin, and formation of peculiar fried-egg-shaped colonies (Razin and Oliver, 1961; Fig. 1). Thin sections of mycoplasmas reveal that the cells are built essentially of three organelles: the cell membrane, ribosomes, and a circular double-stranded DNA molecule (the typical prokaryotic genome; Fig. 2). Because they are devoid of a cell wall, mycoplasmas are Gram negative. Being bounded by a plastic cell membrane only, mycoplasma cells are predominantly spherical (0.3–0.8μm in diameter). Yet, many can be pear-shaped or flask-shaped with terminal tip structures, and form filaments of varying length (some branching) as well as helical filaments (Figs. 3–5). Maintaining such shapes in the absence of a rigid cell wall has indicated long ago the presence of a cytoskeleton in mycoplasmas (Razin, 1978).

Motility and Cytoskeletal Elements

Most mycoplasmas are nonmotile and have no flagella. However, some of the flask-shaped *Mycoplasma* species, including the human and animal pathogens (*M. pneumoniae*, *M. genitalium*, *M. gallisepticum*, *M. pulmonis* and *M. mobile*) glide on liquid-covered surfaces. *Mycoplasma mobile*, isolated from fish gills, is the fastest (2.0–4.5μm/sec). The mechanism of this peculiar gliding motility is still unknown (Trachtenberg, 1998; Miyata, 2002). Although *M. pneumoniae* is motile and exhibits chemotactic behavior, gliding motility genes could not be identified in this mycoplasma, as it is not yet known which genes to look for. Furthermore, none of the components of the chemotactic signal pathway (the Che proteins, which are well conserved among bacteria) or any other two-

Table 1. Major characteristics and taxonomy of the class Mollicutes.

Classification	No. of recognized species	Genome size (kb)	Genome G+C (mol%)	Cholesterol requirement	Distinctive properties	Habitat
Mycoplasmataceae						
Genus I: *Mycoplasma*	107 (11)[a]	580–1350	23–40	Yes	Optimum growth 37°C	Humans and animals
Genus II: *Ureaplasma*	7	760–1170	27–30	Yes	Urease positive	Humans and animals
Entomoplasmataceae						
Genus I: *Entomoplasma*	6	790–1140	27–29	Yes	Optimum growth 30°C	Insects and plants
Genus II: *Mesoplasma*	12	870–1100	27–30	No	Optimum growth 30°C	Insects and plants
Spiroplasmataceae						
Genus I: *Spiroplasma*	34	780–2220	24–31	Yes	Helical filaments	Insects and plants
Acholeplasmataceae						
Genus I: *Acholeplasma*	14	1500–1650	26–36	No	Optimum growth 30–37°C	Animals and plant surfaces
Anaeroplasmataceae						
Genus I: *Anaeroplasma*	4	1500–1600	29–34	Yes	Obligate anaerobes, oxygen sensitive	Bovine–ovine rumen
Genus II: *Asteroleplasma*	1	1500	40	No		
Undefined taxonomic status						
Phytoplasma	ND[b]	530–1185	23–29	ND	Uncultured in vitro	Insects and plants

Abbreviation: ND, not determined.
[a]The number of Candidatus species is given in parentheses and includes the hemoplasmas (*Eperythrozoon* and *Haemobartonella*) recently transferred to the genus *Mycoplasma* (Neimark et al., 2001).
[b]The taxonomic status of the uncultured phytoplasmas has not been finally defined; seven Candidatus *Phytoplasma* spp. have so far been published.
Updated and modified from Razin et al. (1998).

component signal transduction system could be identified in the sequenced *M. pneumoniae* and *M. genitalium* genomes (Himmelreich et al., 1996). The ability of the gliding mycoplasmas to cytadhere mirrors closely their ability to bind to glass, a prerequisite for gliding. Because cytadherence is linked to the tip structure (see below), this attachment organelle probably plays a major role in the gliding mechanism. In fact, the gliding mycoplasmas always move with the attachment organelle at the leading end (Miyata, 2002).

Spiroplasma species are unique in having helical morphology (Fig. 5), rotary motility, and chemotaxis. Motility is characterized by a rapid spinning along the long axis of the cell as well as
Fig. 4. Phase-contrast light microscopy of *Acholeplasma laidlawii* cells. A) Magnification 1250×. (B) Magnification 2700×. Branching filaments and chains of cocci can be seen in these unfixed live broth cultures. From Razin et al. (1966).

Fig. 5. Helical filaments of *S. citri* negatively stained with 2% ammonium molybdate.

by flexional or undulating movements of the helical filaments. The spiroplasma cell can essentially be viewed as a membranal tube (diameter about 0.25 μm) to which a flat cytoskeletal ribbon made of 7 parallel fibrils (diameter 45–50 Å) is attached to its inner side. Both tube and ribbon are mutually coiled into a dynamic helix. The ribbon follows the shortest (inner) helical path (Trachtenberg, 1998). This can be regarded as an internal cytoskeleton that functions as a linear motor as well (Trachtenberg and Gilad, 2001; Trachtenberg et al., 2003a). Upon cell lysis by deoxycholate, spiroplasmas release the fibrils, which consist of a 56-kDa protein. The gene for this protein (*fib*) has been cloned, facilitating the characterization of the structural features of the fibril protein (Williamson et al., 1991). Some information on a gene involved in *S. citri* motility has been obtained through transposon mutagenesis (Jacob et al., 1997; see the section Gene Transfer). An *S. citri* nonmotile mutant was generated by Tn*4001* transposon mutagenesis. The transposon was inserted into a gene named

"*scm1*," encoding a putative polypeptide of about 45 kDa with no significant homology to any known protein. The *scm1* gene was recovered from the wild motile strain and inserted into an *S. citri* cloning vector. Transfection of the nonmotile mutant with this recombinant plasmid restored motility, indicating that the *scm1* gene product is indeed involved in *S. citri* motility, probably serving as an anchor of the cytoskeletal ribbon to the membrane (Trachtenberg and Gilad, 2001). Interestingly, the nonmotile mutant multiplied in the insect vector and was efficiently transmitted to plants, inducing disease and suggesting that spiroplasma motility may not be essential for pathogenicity (Duret et al., 1999).

Williamson et al. (1991) have suggested that an actin-like protein found in spiroplasmas may be linked to the fibrils and associated with motility. The presence of actin-related proteins in prokaryotes in general, and in mollicutes in particular, has long been suspected (Razin, 1978). The complete genomic analyses of *M. genitalium* and *M. pneumoniae* (Fraser et al., 1995; Himmelreich et al., 1996) failed to identify actin-related gene(s), leaving this issue unresolved. Thus far, significant sequence homologies between eukaryotic cytoskeletal proteins and any bacterial protein have not been found (Proft et al., 1995; Mayer et al., 1998), though Wasinger et al. (1995), applying the proteome technology, have suggested the presence of a tubulin-like protein in *M. genitalium*. Recent data, reviewed in Errington (2003) and by Carballido-Lopez and Errington (2003), indicate that actin-like proteins in bacteria form a cytoskeleton that helps to determine cell shape, much as happens in eukaryotic cells. The most studied actin-like proteins are
Fig. 6. Electron micrographs of negatively stained mycoplasmas possessing tip structures. A) *Mycoplasma pulmonis*. Arrows show a thin surface layer on top of a protruding stalk. B) *Mycoplasma gallisepticum*, showing the distinct bleb structure. The particulate surface nap (N) is not restricted to the bleb structure. C) *Mycoplasma pneumoniae*. those encoded by the *mreB* genes that are conserved widely in eubacteria, although they are not ubiquitous. Thus, no *mreB* genes were found in the *M. genitalium* and *M. pneumoniae* genomes. Possibly, mycoplasmas have related proteins forming filamentous structures resembling the Mbl proteins in *Bacillus subtilis* (Errington, 2003), a point awaiting further study.

An important group of pathogenic mycoplasmas, including *M. pneumoniae* and *M. genitalium*, shares a flask- or club-like cell shape with a protruding tip or bleb structure (Fig. 6). These mycoplasmas attach to eukaryotic cells via the tip structure (the mycoplasma's attachment organelle; Fig. 7; see the section Adhesion to Host Cells). Scanning- and transmission electron microscopy of *M. pneumoniae* cells grown on grids treated with 1% Triton X-100 revealed a rod-like tip structure and a network of filamentous strands (Meng and Pfister, 1980). Proteins of this so-called "Triton shell" are apparently
Fig. 7. Thin sections of *Mycoplasma gallisepticum* attaching to tracheal epithelium of chicken seven days postinfection. The mycoplasmas can be seen to attach through their blebs. Minutes lapsed between pictures taken of (a) and (b) 2.8; (c) 3.3; (d) 4.8; (e) 5.3; or (f) 5.5. From Bredt et al. (1973).
cytoskeleton-forming or cytoskeleton-associated proteins. The cytoskeleton-like structure is thought to function in modulating cell shape and to participate in cell division, gliding motility, and the proper localization of adhesins on the mycoplasmal cell surface.

The genomic analysis of *M. pneumoniae* (Himmelreich et al., 1996) has enabled the identification and molecular characterization of major protein building blocks of the cytoskeleton of this mycoplasma. Some of these proteins function as surface-exposed adhesins, including proteins P1 and P30, whereas others, named accessory proteins (designated "HMW1," "HMW2" and "HMW3" and "A," "B" and "C") collectively maintain the proper distribution and disposition of the adhesins in the mycoplasma membrane (Layh-Schmitt and Herrmann, 1994; Layh-Schmitt et al., 1995; Hahn et al., 1998). Additional proteins, named "P65" and "P200" (Proft et al., 1995, 1996) share characteristic structural features with HMW1 and HMW3, suggesting their function as elements of the *M. pneumoniae* cytoskeleton consistent with their presumed scaffolding role (Krause and Balish, 2001; Balish and Krause, 2002).

Recent analysis of the *M. pneumoniae* Triton shell by two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) and mass spectrometry revealed about 100 protein spots. Regula et al. (2001) identified 41 of them. The identified proteins belonged to several functional categories, mainly energy metabolism, translation, and heat-shock response. In addition, lipoproteins and most of the proteins involved in cytadherence were found in this fraction (see the section Adhesion to Host Cells). Quantitatively, the most prevalent proteins were the heat-shock protein DnaK, elongation factor Tu, and subunits α and β of the pyruvate dehydrogenase complex (Regula et al., 2001). Thus, the Triton shell consists of a very heterogeneous complex of proteins as could perhaps be expected from a complex cell fraction isolated according to its insolubility at a low concentration of the mild detergent Triton X-100.
Fig. 9. Schematic presentation of the mode of mycoplasma reproduction. Cells may either divide by binary fission or elongate first to multinucleate filaments and subsequently break up to coccoid bodies. From Razin (1981).

Cell Division

The mode of reproduction of mycoplasmas is essentially no different from that of othe prokaryotes dividing by binary fission. For typical binary fission to occur, cytoplasmic division must be fully synchronized with genome replication, and in mycoplasmas, cytoplasmic division may lag behind genome replication, resulting in the formation of multinucleate filaments. When followed by microcinematography, the transformation of mycoplasma filaments into chains of cocci (a process taking a few minutes) was marked by the appearance of constrictions in the cell membrane at about equal distances along the entire length of the filament (Figs. 8–10). The recent sequencing of several mycoplasma genomes has provided some information on mycoplasmal genes homologous to cell division genes of wall-covered bacteria. The most important finding, perhaps, is that of the *ftsZ* gene in mycoplasmas (Bork et al., 1995; Fraser et al., 1995; Himmelreich et al., 1996; Wang and Lutkenhaus, 1996; Kukekova et al., 1999). In eubacteria, FtsZ is a polymer-forming, guanosine triphosphate (GTP)-hydrolyzing protein with tubulin-like elements; it is localized to the

a
Fig. 10. Constrictions in the negatively stained helical filament of *Spiroplasma citri* preceding its division. Bar = 500 nm. From Razin (1978) reprinted with the courtesy of I. M. Lee.

site of septation and forms a constricting ring (the Z ring) between the dividing cells. The finding of *ftsZ* in mollicutes indicates that it is a highly conserved and ubiquitous gene fulfilling a key role in prokaryote cell division. Yet, generalizations are risky as FtsZ could not be found in *Ureaplasma* (Glass et al., 2000) and *Chlamydia* (Galperin, 2001). Of the additional genes associated with cell division in eubacteria (*ftsA*, *ftsH*, *ftsI*, *ftsQ*, *ftsW* and *ftsY*), *ftsH* was identified in *M. pneumoniae* (Himmelreich et al., 1996) and *M. capricolum* (Bork et al., 1995), and *ftsY* in *M. genitalium* (Fraser et al., 1995), *M. pneumoniae* (Himmelreich et al., 1996) and *U. urealyticum* (Glass et al., 2000). More recently, the *ftsY* of *M. mycoides* subsp. *mycoides* was cloned and characterized, and its role in protein targeting by complexing with the signal-recognition particle (SRP) was investigated (Macao et al., 1997). Applying the proteome approach, Wasinger et al. (1995) proposed the presence of a tubulin-like protein in *M. genitalium*. It has been suggested that the FtsZ protein of prokaryotes is a tubulin homologue, but the tubular structures formed by FtsZ in vitro are substantially different from microtubules, and the similarity between FtsZ and tubulin sequences is barely significant (Gupta and Soltys, 1996). Recent data (reviewed in Garballido-Lopez and Errington [2003]) have shed new light on the identity of the components of the bacterial cytoskeleton. Apparently, the bacterial FtsZ can be considered as the bacterial ancestor of tubulin, and the prokaryotic protein MreB is the bacterial equivalent of actin. Despite a weak sequence similarity (explaining the failure to identify these proteins as tubulin and actin in prokaryotic genomic annotations), FtsZ and MreB have structural, biochemical and functional properties strikingly similar to those of their eukaryotic counterparts. FtsZ undergoes tubulin-like GTP-dependent polymerization into a ring structure that constricts at septation and direct cytokinesis in almost all bacteria examined. MreB proteins undergo actin-like

ATP-dependent polymerization into helical structures that control morphogenesis in nonspherical bacteria (Garballido-Lopez and Errington, 2003).

An integral part of cell division is chromosome replication and partition into daughter cells. Chromosome replication and partitioning in mollicutes follows the basic principles of binary fission (Miyata and Seto, 1999; Miyata, 2002). The velocity of the DNA replication fork progression in *M. capricolum* was about 6kb/min, about 10 times slower than that of *E. coli*. The time required for one round of chromosome replication was estimated to be about 94 min, and *M. capricolum* is considered among the fastest growing mollicutes (Seto and Miyata, 1998). While the outline of DNA replication in mycoplasmas is presumably similar to that of walled bacteria, the coupling of chromosome replication and cell division in mycoplasmas is not so simple. The lack of a peptidoglycan layer, which plays important roles in nucleoid partitioning and cell division, argues that the concepts developed for walled bacteria cannot be simply applied to mycoplasmas (Seto and Miyata, 1999). Nucleoid movement occurs in combination with cell elongation, but the kind of force that propels and localizes the nucleoids is not known. Mycoplasma cells apparently lack a solid structure like the periseptal annulus in *E. coli*, because they do not have the peptidoglycan layer. Possibly, the fibrillar cytoskeletal structure observed in *M. pneumoniae* and *M. gallisepticum* is involved in nucleoid migration (Seto and Miyata, 1999).

Mycoplasmas carry topoisomerases (see the section DNA Replication and Repair) capable of relaxing superhelical DNA, fulfilling an essential role in cell division (Bailey et al., 1996). In mycoplasma species possessing a tip structure, duplication of this organelle is a prerequisite for cell division. Observation of the cell division process in *M. pneumoniae* suggests that the nascent organelle is formed next to the old one and then migrates to the opposite cell pole before binary fission of the cell takes place (Seto et al., 2001). What is the motive force propelling the migration of the tip organelle? This is certainly an intriguing question for which no answer is as yet available. One possibility is to associate it with the gliding motility of this mycoplasma. Another possibility is to associate it with the filamentous structures taking part in the cell division process (Seto et al., 2001). In conclusion, the factors coordinating the cell division process in mollicutes are still rather far from being clearly understood, inasmuch as genetic information has just started to accumulate and is still fragmentary and not entirely analyzed and evaluated.

Phylogeny and Taxonomy

Phylogeny

The early studies of Woese et al. (1980), comparing 16S rRNA sequences of mollicutes have provided the basis for mycoplasma phylogeny. Accordingly, the mycoplasmas arose at a node on the branch of Gram-positive bacteria having a low G+C genome. This branch of the *Lactobacillus* group contains *Lactobacillus*, *Bacillus* and *Streptococcus* species, and two rather unusual *Clostridium* species, *C. innocuum* and *C. ramosum*. Mycoplasma phylogeny from this node took place by degenerative or reductive evolution, characterized by a rapid tempo, in line with the marked genotypic and phenotypic variability characterizing the mollicutes as a group (Woese et al., 1985; Woese, 1987). Phylogenetic trees of Mollicutes are still based mostly on 16S rRNA sequences (Fig. 11), but several other conserved gene sequences (e.g., *tuf* genes) have been used for this purpose (Kamla et al., 1996). According to 16S rRNA sequences, the mollicutes are divided into five phylogenetic units (clades): the asteroleplasma, spiroplasma, pneumonia, hominis, and anaeroplasma clades (Weisburg et al., 1989; Johansson and Petersson, 2002).

A scheme of mycoplasma evolution has been proposed by Maniloff (2002). Accordingly, the ancestral mycoplasma arose from the *Streptococcus* phylogenetic branch about 600 million years ago, having probably a genome of about 2000 kb. The mycoplasma branch split later into two major branches: one branch led to the *Asteroleplasma*, *Anaeroplasma* and *Acholeplasma* branches, and the other led to the *Spiroplasma*, *Entomoplasma* and *Mycoplasma* branches. The phytoplasmas subsequently arose from the *Acholeplasma* branch, and *Ureaplasma* arose from the *Mycoplasma* branch. In both major branches, genome reductions had occurred independently during their degenerate evolution. Thus, degenerate evolution of the *Acholeplasma-Anaeroplasma* branch, taking place after the appearance of flowering plants, has led to the phytoplasmas with 600–1200-kb genomes, while evolution of the second major branch produced the *Spiroplasma* branch with 1000–2000-kb genomes and the *Entomoplasma*, *Mesoplasma*, *Mycoplasma* and *Ureaplasma* branches with 600–1200-kb genomes. Clearly, the time at which transition to rapid evolution occurred correlate with major paleontological events in the evolution of the flora and fauna that formed ecosystems for lineages of each branch. Thus, the *Spiroplasma* and *Entomoplasma* transition to rapid evolution occurred about 100 million years ago soon after the appearance of the first flowering plants and their associated insects. The

increase in potential hosts presumably provided niches for the selection of new lineages. Although all the above should be taken as hypothetical assessments, they emphasize a cardinal point: the mollicutes are relatively late evolutionary products.

The voluminous data on the molecular properties of mycoplasmas derived from the recent genomic analyses have provided strong support for the close phylogenetic relatedness of mollicutes to Gram-positive bacteria. Thus, in the majority of cases where *M. genitalium* coding regions matched sequences of both *Escherichia coli* and *Bacillus* species, the better match was to sequences of *Bacillus* (average, 62% similarity) than to sequences of *E. coli* (average, 56% similarity; Fraser et al., 1995). Other findings supporting this thesis are brought up in the Genetics and Physiology sections of this chapter.

Taxonomy

There is a consensus among bacterial taxonomists that the complete sequences of bacterial genomes will form the basis for phylogeny and, ultimately, taxonomy. Yet, as long as complete genomic sequences are available for only a relatively small number of bacteria, current bacterial taxonomy, including that of mollicutes, must rely on the combination of phenotypic characteristics and phylogenetic data based on partial genomic sequences, mostly those of the conserved ribosomal RNA genes. Detailed descriptions and evaluations of current molecular methods in taxonomy, phylogeny and diagnostics of mollicutes can be found in Razin (1992), in the two volumes of *Molecular and Diagnostic Procedures in Mycoplasmology* (Razin and Tully, 1995; Tully and Razin, 1996) and in *Mycoplasma Protocols* (Miles and Nicholas, 1998).

Though the availability of complete genomic sequences is expected to provide a sound basis for establishing phylogenetic relatedness among bacterial species and consequently enable the construction of taxonomic entities based on phylogeny, the way to achieve this has not been worked out as yet because of several key problems. Thus, the current, somewhat arbitrary definition of the basic taxonomic entity (i.e., the bacterial species) includes all strains with DNA having approximately 70% or higher homology and a melting temperature change (δT_m) of 5°C or lower (Razin, 1992b). There can be little doubt that this definition will have to be modified once comparison of entire genomic sequences replaces the cumbersome and not too accurate determination of genetic homology based on DNA-DNA hybridization tests. Yet, as long as the number of bacterial genomes sequenced remains small, there is still more than enough
Fig. 11. Phylogenetic tree of mycoplasmas based on 16S rRNA sequences. Representatives of the closely related genera *Clostridium* and *Eubacterium* are also included in the tree. From Johansson et al. (1998).

time to work out a solution to the above problem. Comparison of the genomic sequences of *M. genitalium* and *M. pneumoniae* (Himmelreich et al., 1997; Herrmann and Reiner, 1998) has revealed the significant genomic relatedness of these mycoplasmas and underlines the problems that taxonomists may face when using comparative genomic data to redefine taxonomic entities, including that of a bacterial species.

Conserved Genes as Molecular Markers

The great weight given to 16S rDNA sequences in mycoplasma phylogeny, taxonomy and species identification (Razin, 1992; Johansson and Petersson, 2002) has led the International Committee on Systematic Bacteriology—Subcommittee on the Taxonomy of Mollicutes (1997)—to recommend the inclusion of the 16S rDNA sequence in any description of a new mollicute species. K.-E. Johansson has been compiling a database of 16S rDNA sequences of the recognized *Mycoplasma* species deposited at GenBank (Johansson and Petersson, 2002).

A most important contribution of 16S rRNA gene sequences to mollicute phylogeny and taxonomy has been the placing of the uncultured phytoplasmas (as a distinct monophyletic clade) within Mollicutes, closely related to the acholeplasmas (Lee et al., 2000; Seemuller et al., 2002). This conclusion has been supported by the small genome size of phytoplasmas, resembling that of the culturable mollicutes (Marcone et al., 1999), by the finding of only two rRNA operons in the phytoplasmas, and a tRNA[Ile] gene in the spacer region between the 16S and 23S rRNA genes (Ho et al., 2001; Seemuller et al., 2002), a feature found also in acholeplasmas. The deduced amino acid sequences of some of the highly conserved ribosomal protein genes also indicated that the phytoplasmas are more closely related to *Acholeplasma laidlawii* than to *Mycoplasma* species. Like acholeplasmas, phytoplasmas read UGA as a stop codon rather than a tryptophan codon. The polymerase chain reaction (PCR)-amplified 16S rRNA gene sequences delineated (within the phytoplasma clade) 20 major phylogenetic groups or subclades. This number is generally in accord with the phytoplasma strain clusters established by DNA homology, restriction enzyme analyses (REA) of PCR-amplified 16S rRNA genes, and sequences of the 16S-23S intergenic spacer regions (Seemuller et al., 2002). The taxonomic implications of these studies are that the phytoplasmas should be distinguished at the minimal taxonomic level of a genus, and each phytoplasma subclade should represent at least one distinct species (International Committee, 1997). However, in the absence of the phenotypic markers used to classify mollicutes, taxonomic affiliations cannot be resolved at the present time in the conventional way. Thus, a provisional classification of the uncultured phytoplasmas may be introduced by applying the Candidatus category proposed for classification of uncultured bacteria (International Committee, 1997). So far, seven Candidatus species names for phytoplasmas have been published (Seemuller et al., 2002; Table 1). The phytoplasma case demonstrates well the revolution occurring in bacterial taxonomy, where molecular data suffice for laying the phylogenetic and taxonomic basis for classification of a group of organisms for which very few phenotypic characteristics are available. On the other hand, the difficulty of basing classification on sequence data of uncultured organisms should not be ignored, as there is a danger that a mixture of phylogenetically diverse organisms may be considered erroneously as a single organism. Such chimeric sequences are easily recognized when reference sequences from cultured organisms are available for all components of the chimera. When such references are not available, it may be difficult to decide which of the new sequences represent those from a genuinely independent organism and which ones come from an artificial chimera.

The molecular approach to phytoplasma classification has recently been applied also to the uncultured hemoplasmas (Neimark et al., 2001; see the sections Habitats and Ecology) comprising the *Haemobartonella* and the *Eperythrozoon* species. These bacteria have been classified until recently as rickettsiae (order Rickettsiales) because of their small size, staining properties, obligate parasitism, and hemotrophic character. Several of them are transmitted by blood-feeding arthropods. However, phylogenetic analyses of 16S rRNA gene sequences have revealed that *Haemobartonella* and *Eperythrozoon* species are not rickettsiae but are rather mycoplasmas (Neimark and Kocan, 1997; Rikihisa et al., 1997) with the highest similarity scores with members of the pneumonia clade, closest to *M. fastidiosum* and *M. cavipharyngis* (Johansson et al., 1999; Neimark et al., 2002). Since the hemoplasmas have not been cultured as yet, naming of new species should be included in the Candidatus category (Neimark et al., 2001, 2002).

The morphology of the hemoplasmas is of small coccoid organisms attached to erythrocytes, while a few may appear free in the erythrocyte cytoplasm. The individual coccoid cells can aggregate to give the appearance of short chains and small clusters of rod-shaped organisms. Electron microscopy shows the coccoid organisms to be about 0.3 μm in diameter with no cell wall. This morphology corresponds well with that of mycoplasmas (Messick et al., 2002;

Neimark et al., 2002). Although some *Haemo-bartonella* and *Eperythrozoon* species can cause overt disease in healthy immunocompetent animals, the majority of these species produce chronic asymptomatic infections. Clinical disease usually includes hemolytic anemia that varies from mild to severe.

Although the 16S rRNA sequences have proved to be very effective tools in the phylogeny and taxonomy of mollicutes, the feeling is that additional phylogenetic markers are desirable to support the conclusions based on the 16S rRNA data. In fact, such markers have already been applied, including the conserved ribosomal protein genes (Gundersen et al., 1996), elongation factor EF-Tu (*tuf*) gene (Kamla et al., 1996), heat shock protein gene *hsp70* (Falah and Gupta, 1997), *ftsZ* gene (Kukekova et al., 1999), DNA repair *uvrC* gene (Subramaniam et al., 1998), ribonuclease P (*rnpB*) gene (Birkenheuer et al., 2002), *rpoB* gene encoding the β subunit of RNA polymerase (Kim et al., 2003), and 16S-23S rRNA intergenic sequences (Harasawa, 2000). Use of these markers has supplemented and complemented the 16S rRNA comparative data. A priori, wobble in the genetic code permits more variations in protein gene sequences, even of highly conserved genes, than is possible in rRNA sequences. Thus, even though the ribosomal protein-encoding genes are conserved, they vary in size and primary sequence more than the 16S rRNA genes. Therefore, the ribosomal protein genes have a greater potential to reveal variations among closely related strains. Likewise, the intergenic spacer region located between the 16S and 23S rRNA genes, being less subjected to evolutionary constraints than the genes themselves, exhibits greater sequence variation, a property of use in strain differentiation (Harasawa, 2000).

Generally, housekeeping or constitutive genes, which are expressed in all living organisms because they provide essential functions (such as replication, transcription and translation), are good candidates for genetic differentiation of species. The *uvrC* gene, which encodes deoxyribodipyrimidine photolyase, is well conserved within each species, but the gene is sufficiently different between species, so that it may serve as an effective taxonomic probe (Subramaniam et al., 1998). The heat shock Hsp70 family of proteins shows, perhaps, the highest degree of sequence conservation and is therefore well suited for examining deep phylogenetic relationships. The application of the *hsp70* gene to phylogenetic analysis of mollicutes has strengthened considerably the evidence gained through the 16S rRNA sequence analyses that mollicutes are evolutionarily closely related to the Gram-positive bacteria (Falah and Gupta, 1997).

Intraspecies Genetic Heterogeneity

Factors such as the arbitrary and somewhat vague definition of a bacterial species, the frequent and significant chromosomal rearrangements taking place in mycoplasmas (see the section Chromosomal Rearrangements), and the frequent integration of extrachromosomal elements into the mycoplasmal genome are conducive to the finding of intraspecies genotypic heterogeneity. Intraspecies genotypic heterogeneity, noticeable on serological testing and electrophoretic analysis of cell proteins, became much clearer through the application of more sensitive molecular tools such as restriction fragment length polymorphism (RFLP), restriction-modification activity profiles, and sequence analysis of conserved genes, species-specific protein genes, genomic physical maps, etc. (Razin, 1992; see the section Identification). These tests have provided epidemiologists with very sensitive tools to distinguish strains of interest in the clinic and in the field (see figures of RFLPs in the section Identification). On the basis of such molecular tools, the clinically important human *Ureaplasma urealyticum* species, long known to consist of two clusters of serovars, has recently been divided into two species, *U. urealyticum* and *U. parvum* (Robertson et al., 2001). Another example of clinical importance concerns the difference between the European and African-Australian strains of *M. mycoides* subsp. *mycoides* SC. The African-Australian strains are significantly more virulent than the European strains and cause more serious cases of contagious bovine pleuropneumonia. Recent studies indicate that the chromosome of the European strains lacks an 8.84-kb segment found in the African strains that includes two open reading frames (ORFs) of putative ATP-binding cassette (ABC) transporters and several genes encoding membrane proteins and an insertion element. This chromosomal deletion is associated with a deficiency in glycerol uptake and metabolism in the European strains, possibly explaining their lower pathogenicity (Vilei et al., 2000; see the section Pathogenicity).

Metabolic and Phenotypic Markers

The present tendency to depend on direct genomic analysis, made available by the dramatic advancements of molecular genetic methodology, has discouraged further development of classical taxonomic tools based on determination of nutritional requirements and enzymatic activities (Razin, 1992). Because they reflect the expression of specific genes and are thus liable to changes, electrophoretic cell

protein profiles are now used less extensively as taxonomic tools than they were in the 1970s and early 1980s. Protein genes themselves can now be sequenced and cloned and thus yield to more direct comparison. Yet, the recent development of the proteome approach to genomic analysis may revive the use of electrophoretic patterns of cell proteins as a taxonomic and phylogenetic tool (see the section Transcriptomes and Proteomes).

Note also that distinguishing members of the class Mollicutes by their metabolic characteristics has been generally of limited phylogenetic and taxonomic usefulness. A few exceptions include the ability to ferment glucose, to hydrolyze arginine and urea, and the dependence on cholesterol for growth and anaerobiosis. Cellular localization of reduced nicotinamide adenine dinucleotide (NADH) oxidase activity has also been of help in classification of mollicutes at and above the genus level. Though *Acholeplasma* species resemble other prokaryotes in having the NADH oxidase localized in the plasma membrane, this enzymatic activity is located in the cytoplasm of *Mycoplasma*, *Spiroplasma* and *Ureaplasma* species. The finding of this activity in the cytoplasm of the *Mesoplasma* and *Entomoplasma* species has helped to distinguish these newly described genera from *Acholeplasma* species (Tully et al., 1993; Pollack et al., 1996). Extensive studies carried out in the laboratory of J. D. Pollack (reviewed in Pollack [2002b]) were aimed at the finding of mycoplasmal enzymatic activities useful for the differentiation of mollicutes genera. Several activities (endowed with such a potential) were defined but so far not put into general use.

At the species level, serologic relatedness has until recently overshadowed all other features used in routine mollicute identification, but the weight given to determination of molecular properties in mollicute classification and identification is steadily increasing (Razin, 1992). The high rate of surface antigenic variation characterizing mollicutes (see the section Antigenic Variation) may impose some limitations on the use of monoclonal antibodies to surface antigens as tools in mycoplasma identification (Rosengarten and Yogev, 1996), difficulties usually not encountered when polyclonal antibodies are used (International Committee, 1997, 2000). To limit the number of serological tests and more so the large number of specific antisera currently required for the definition of new mollicute species, the International Committee on the Taxonomy of Mollicutes (2001) has agreed that the new isolate can be placed in the proper phylogenetic clade on the basis of 16S rRNA sequences and serological cross-testing can be restricted to members of this clade.

The weight to be given to cholesterol requirement in mollicute taxonomy illustrates well the conflict that may occur between taxonomy based on phenotypic characteristics and that based on molecular phylogenetic data. Cholesterol requirement has been considered for a long time as a major criterion in establishing high taxonomic groupings within the Mollicutes (Razin and Freundt, 1984a). Recent findings weaken the high status of cholesterol requirement in mollicute classification. Thus, the cholesterol-nonrequiring mesoplasmas, considered previously as acholeplasmas, were shown to possess molecular properties very different from those of the classic acholeplasmas, requiring their taxonomic separation (Tully et al., 1993; Pollack et al., 1996). In addition, several *Spiroplasma* species were shown to grow in the absence of cholesterol (Tully et al., 1993). These data suggest that nutritional dependency on exogenous sterols is a trait that has arisen independently several times during the evolution of mollicutes, as it occurs in at least three different phylogenetic groups. Thus, cholesterol requirement apparently should not be used as a sole definitive criterion in defining higher taxa of the class Mollicutes but rather serve as one of a matrix of characters in mollicute classification. Consequently, though nutritional requirements are the most practical traits used to assess in routine laboratory tests, they may not always be reliable indicators of phylogenetic relationships.

Blending Taxonomy with Phylogeny

Whereas basing bacterial taxonomy on phylogeny is generally thought to be both inevitable and advantageous, bacterial taxonomists disagree about whether the time is ripe for radical changes in bacterial taxonomy (for detailed discussion, see Razin [1992]). The taxonomic status of the *Mycoplasma mycoides* cluster illustrates well the problem. The Mollicutes phylogenetic tree based on 16S rDNA sequences has suggested that the *M. mycoides* cluster is phylogenetically related to the genus *Spiroplasma* (Weisburg et al., 1989). However, the proposal to reclassify this cluster accordingly has not been adopted by the International Committee (1997), arguing that such a reclassification would create considerable problems in diagnostic veterinary medicine. Likewise, reassignment of all other *Mycoplasma* species to a new genus would have unacceptable consequences in human and veterinary medicine. For the time being, a polyphasic classification based only partly on phylogeny is recommended, striving to fit in mollicute taxa as much as possible into phylogenetic classification.

Habitats and Ecology

Mycoplasmas are widespread in nature as parasites of humans (Blanchard and Bebear, 2002), mammals (Frey, 2002), reptiles (Brown et al., 2001), fish, arthropods and plants (Tully, 1996; Seemuller et al., 2002). The list of hosts known to harbor mycoplasmas is continuously increasing, as does the number of established mollicute species (about 200 so far; Table 1). It is widely agreed that the mollicutes that have already been characterized and taxonomically defined constitute only a part, apparently a minor one, of the mollicutes living in nature (Razin, 1992). The higher the number of established mollicute species, the harder it gets to fulfill the minimal requirements for establishing new species (International Committee, 1995). A large battery of species-specific antisera and seed is needed for this task. The introduction of molecular tools to taxonomy, including the comparison of 16S rRNA and of other conserved gene sequences, genomic restriction patterns, etc. (Razin, 1992, 1994) has already been found effective in species and strain identification, decreasing the weight of serology in species and strain identification and classification (see the sections Phylogeny and Taxonomy and Identification).

Uncultured Mollicutes

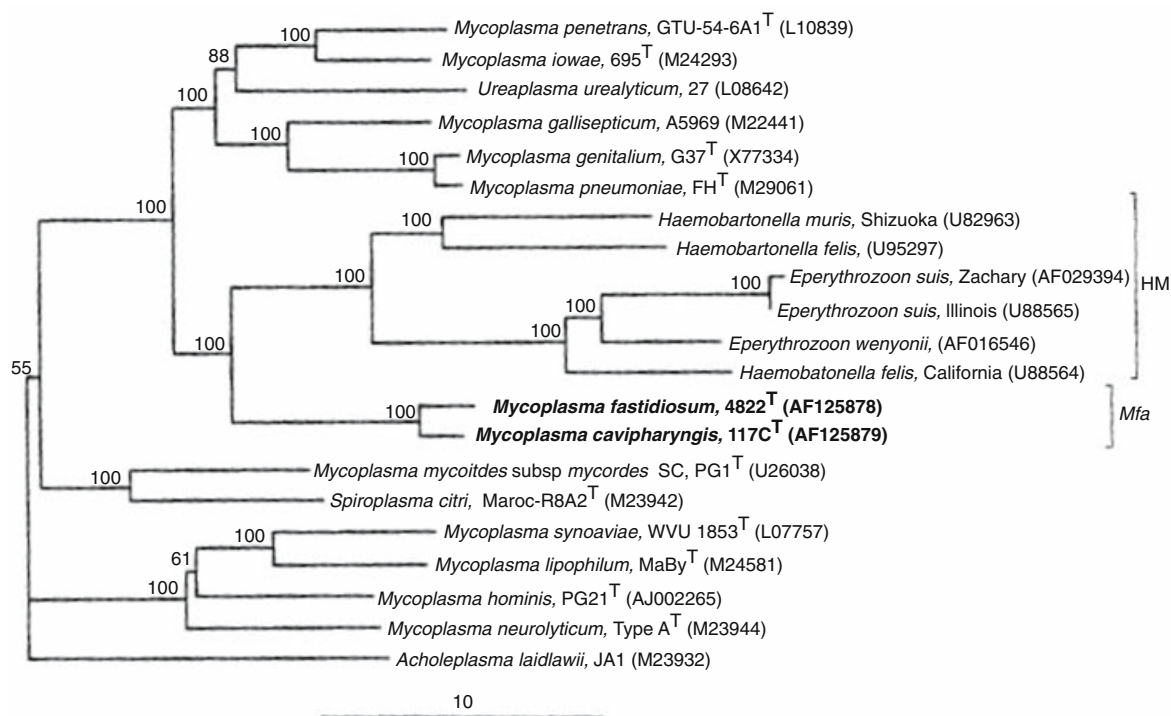
The successful application of genomic analysis methodology has led to the identification of the uncultured plant and insect MLOs as bona fide mycoplasmas (see Phylogeny and Taxonomy), showing how the identity of other mycoplasma-like organisms can be confirmed as mollicutes. Thus, the grey lung virus infection of mice, caused by a mycoplasma-like agent (as seen in thin sections of lung material), but resisting cultivation, has been identified as a mycoplasma on the basis of its genome size and 16S rRNA sequence. Classification of this organism as "Candidatus *Mycoplasma ravipulmonis*," the "Candidatus" taxon being reserved for classification of uncultured prokaryotes (Neimark et al., 1998), has been proposed. Most important are the findings, based on 16S rRNA sequence analysis, that *Haemobartonella* and *Eperythrozoon* (well-known uncultured wall-less pathogenic bacteria, infecting erythrocytes of a wide range of vertebrate hosts) are phylogenetically closely related to Mollicutes rather than to rickettsia and should therefore be reclassified as *Mycoplasma* species (Neimark and Kocan, 1997; Rikihisa et al., 1997). According to a 16S rRNA phylogenetic tree (Fig. 12), these two hemotropic bacteria are closest to the *M. fastidiosum–M.*


Fig. 12. Phylogenetic tree based on 16S rRNA sequences showing the relations between *Eperythrozoon* spp. and *Haemobartonella* spp. and mycoplasmas. According to the dendogram, the hemotropic bacteria are closest to the *M. fastidiosum–M. cavipharyngis* cluster. From Johansson et al. (1999).

cavipharyngis cluster (Johansson et al., 1999). The inclusion of these hemotropic agents in Mollicutes represents an entirely new group of pathogens among the mycoplasmas (see also the section Phylogeny and Taxonomy).

Host and Tissue Specificity

Mycoplasmas usually exhibit a rather strict host and tissue specificity, probably reflecting their nutritionally exacting nature and obligate parasitic mode of life. However, there are numerous examples of mycoplasmas present in hosts and tissues different from their normal habitats (Tully, 1996). The primary habitats of human and animal mycoplasmas are the mucous surfaces of the respiratory and urogenital tracts, the eyes, alimentary canal, mammary glands, and the joints. The obligatory anaerobic anaeroplasmas have so far been found only in the bovine and ovine rumen (Table 1). Spiroplasmas and phytoplasmas are widespread in the gut, hemocoel, and salivary glands of arthropods. The spiroplasmas and phytoplasmas may be introduced through sap-sucking insects to the phloem tissues of plants, causing disease (Tully and Whitcomb, 1992; Seemuller et al., 2002). Accompanying the increase in the number of patients suffering from various types of immunodeficiencies, associated with hypogammaglobulinemia, acquired immune immunodeficiency syndrome (AIDS), and treatment with immunosuppressive medication is the increase in the number of reports on the isolation of mycoplasmas from organs different from their usual habitats. Thus, mycoplasmas and ureaplasmas belonging to the normal urogenital flora have been isolated from the blood of patients suffering from AIDS or treated with immunosuppressive drugs. Hypogammaglobulinemic and immunocompromised patients become susceptible to infections by the urogenital mycoplasmas *M. hominis* and *U. urealyticum*, spreading into and causing disease in organs such as the respiratory tract and joints (Gass et al., 1996; Frangogiannis and Cate, 1998).

Mycoplasmas Infecting Cell Cultures

Cell cultures infected by mycoplasmas constitute an artificial unnatural habitat. The serious problems created by the persistent and hard to detect infections of cell cultures are reflected in the voluminous literature on this subject. Reports from various countries show that 10–87% of cell cultures are infected by mycoplasmas (Barile and Rottem, 1993; Uphoff and Drexler, 2002). The percentage of infected cell cultures depends to a large extent on the population of cell cultures assayed, control practices used, and

efficiency of the assay procedures applied. The mycoplasma species infecting cell cultures have remained essentially the same, with *M. hyorhinis*, *M. orale*, *M. arginini* and *A. laidlawii* being the dominant contaminants. *Mycoplasma fermentans*, a mycoplasma suspected to be a cofactor in AIDS (see the section Disease Manifestations), is increasingly found as a contaminant infecting cell cultures and is therefore of particular interest in studying the possible origin of contaminating mycoplasmas. Elimination of mycoplasmas from infected cell cultures by antimycoplasmal agents is time-consuming and often unsuccessful (Uphoff et al., 2002) probably because a small percentage of the contaminating mycoplasmas survive in an intracellular location.

The hard-to-detect mycoplasma contamination of stock virus and chlamydia kept in cell cultures could, of course, pose serious problems when these stock cultures are used as seed and reference antigens (Huniche et al., 1998). Mycoplasmas infecting the cell cultures were shown to produce or induce numerous factors and enzymatic activities reported in the cultures. For example, a protein detected in tumor cell lines, named "M161Ag" activated human complement and induced proinflammatory cytokines. This protein, originally thought to be produced by the cell line, was later shown to originate in *M. fermentans* latently infecting the tumor cell cultures (Matsumoto and Seya, 1999). Tests based on conversion of radiolabeled arginine to citrulline for the presence of inducible nitric oxide synthase in neonatal foreskin fibroblast cultures, were compromised by the presence of contaminating mycoplasmas that convert arginine to citrulline by the arginine dihydrolase system (Choi et al., 1998). Thus, the need to take all precautions to prevent mycoplasma contamination of cell cultures cannot be overemphasized.

Human and Animal Mycoplasmas

Table 2 lists the mycoplasmas found in humans. Some of these mycoplasmas may cause disease whereas others are commensals, constituting part of the normal flora of the oropharynx and the urogenital tract. Some of the human mycoplasmas shown in Table 2 can also be isolated from nonhuman primates.

Farm animals, cattle, sheep, goats, horses, swine, chickens and turkeys harbor a great variety of mollicutes, many of them pathogenic. Mollicutes can be found also in dogs, cats, small laboratory animals, either as commensals or pathogens. A mollicute flora has been defined in a wide variety of wild animals, including elephants, lions, seals, crocodiles, turtles and

Table 2. Common human mollicutes.[a]

Species	Primary organ	Pathogenicity
M. pneumoniae	Lung, oropharynx	Primary atypical pneumonia
M. genitalium	Urogenital tract	Nongonococcal urethritis in men and PID in women
M. hominis	Urogenital tract	Usually commensal, may cause infections on reaching internal organs (salpingitis)
M. fermentans	Urogenital tract, respiratory tract	Cofactor in AIDS activation? Arthritis?
M. penetrans	Urogenital tract? Colon?	Cofactor in AIDS activation?
M. salivarium	Buccal cavity	Commensal. Periodontal disease?
M. orale	Buccal cavity	Commensal
Ureaplasma urealyticum and Ureaplasma parvum	Urogenital tract, placenta	Nongonococcal urethritis, neonatal lung and brain infections

Abbreviations: PID, pelvic inflammatory disease; and AIDS, acquired immunodeficiency syndrome.
[a]Commensal mycoplasmas less commonly isolated from humans: *M. buccale*, *M. faucium* and *M. lipophilum* from the oropharynx; *M. primatum* and *M. spermatophilum* from the genitals and *M. pirum* from blood (see Blanchard and Bebear [2002]). A novel, yet unnamed, *Mycoplasma* species has recently been isolated from sputa of immunocompromised patients suffering from chronic bronchitis (Webster et al., 2003).

prawns. In essence, mollicutes may be ubiquitous in the animal world. Apparently the main factor determining whether an animal is added to the long list of animals harboring mycoplasmas is the willingness of the mycoplasmologist to isolate and characterize the mycoplasmas from the animal. Interestingly, the laboratory rabbit represents an exception among the animals so far studied, as it appears to be free of mycoplasmas. Lack of a natural mycoplasma flora makes the rabbit a preferred animal for production of specific antisera to mycoplasmas. For detailed descriptions of the mollicute flora of humans and animals, see Blanchard and Bebear (2002) and Frey (2002).

Mycoplasmas in Arthropods and Plants

Arthropods are major habitats of mollicutes, including the helical spiroplasmas, sterol-nonrequiring mesoplasmas, sterol-requiring entomoplasmas, and the uncultured phytoplasmas (Table 1). The spiroplasma group is apparently one of the most abundant groups of microbes. Spiroplasmas have been reported from species of six evolutionary advanced insect orders: *Hymenoptera* (honeybees and wasps), *Coleoptera* (beetles), *Diptera* (flies and blood-sucking insects), *Lepidoptera* (butterflies), *Homoptera* (leafhoppers), and *Hemiptera* (leaf bugs). Spiroplasmas were also isolated from ticks, but it is not clear whether spiroplasma occurrence relates to the developmental stages of the tick or whether vertebrates play a role in maintaining the spiroplasmas in the ticks (Tully and Whitcomb, 1992; Gasparich, 2002).

Classification of spiroplasmas was based for a long time mostly on grouping, and official binomial names were coined with caution. This policy has been changed, already yielding 34 named *Spiroplasma* species (Table 3), and this number is expected to increase to at least 40 (International Committee, 2000).

Spiroplasmas are most frequently found in the insect gut, less frequently in the hemolymph, and occasionally in various organs such as the salivary glands. Spiroplasmas in the insect gut are generally acquired by natural feeding, either from plant tissue, nectar, or ingestion of other insects. Some spiroplasmas, like the honeybee spiroplasmas, are pathogenic and may kill their insect hosts or eliminate the male progeny of infected *Drosophila* (Williamson et al., 1999), whereas others are considered commensals, even when present in large numbers in the hemolymph (Table 3). Spiroplasmas involved in vector-transmitted plant diseases (citrus stubborn and corn stunt) must pass through a complex biological cycle that involves uptake from the sieve cells of the plant phloem and subsequent passage to, or multiplication in, the insect alimentary tract, gut epithelium, basement membrane, hemocoel, and possibly some internal organs. At this phase of infection the spiroplasmas lose their helicity and appear as rounded, pleomorphic bodies with a reticulated internal structure, most frequently found in membrane-bound pockets in the insect cell (Kwon et al., 1999). The organisms eventually pass from the hemocoel into the ciliary cells and salivary duct, from which reinoculation of healthy plants takes place. Induction of disease in the plant is the rule. The symptoms in plants include chlorosis, leaf mottling, proliferation of growing points and general stunting (Tully and Whitcomb, 1992).

Many spiroplasmas observed in the hemolymph of insects have resisted cultivation. The sex-ratio spiroplasma of *Drosophila* spp., one of the first spiroplasmas to be described, was cultivated in vitro following the initial cocultivation with insect cell lines (see Isolation).

Table 3. *Spiroplasma* species, their hosts and disease manifestations.

Species	Principal host	Disease manifestations
S. alleghenense	*Panorpa helena* scorpion fly	U
S. apis	Bees and flowers	"May disease" of bees
S. cantharicola	*Cantharis* beetle	U
S. chinense	*Calystegia hederaceae* flowers	U
S. chrysopicola	*Chrysops* sp. deerfly	U
S. citri	Dicots and *Circulifer* leafhoppers	Citrus stubborn
S. clarkii	*Cotinus* beetle	U
S. corrscae	*Ellichnia corrusca* firefly	U

Data from Williamson et al. (1998).

Spiroplasma occurrence in plant hosts is based on either invasion of the plant sieve tubes in the course of a biological cycle involving the feeding of homopterous insects (leafhoppers) or on external contamination of floral parts deposited by flower-visiting insects. Only spiroplasma invasion into plant sieve tubes results in disease, as seen in various citrus plant diseases with *S. citri*, in corn stunt disease with *S. kunkelii*, and in the so-called "periwinkle disease" with *S. phoeniceum*. Numerous other *Spiroplasma* species have been isolated from flower surfaces and nectar, but no evidence is currently available that these organisms also occur within internal plant tissues (Table 3). However, some normal flower-inhabiting spiroplasmas acquired by specific insects act as pathogens, as is the case of *S. apis* strains acquired by honeybees (Tully, 1996). A rather intriguing issue concerns the possible occurrence and pathogenicity of spiroplasmas in animals. Only one spiroplasma, *S. mirum* strain SMCA has been shown to experimentally infect suckling mice causing cataracts (Gasparich 2002). Claims associating spiroplasmas with transmissible human spongiform encephalopathies have been repeatedly made, the most recent claim being based on positive PCR tests for *S. mirum* 16S rDNA in human brain samples (Bastian and Foster, 2001). Spiroplasma-like structures could also be demonstrated in a cataract in a premature baby, a finding supported by positive PCR with the 16S rDNA of *Spiroplasma* group VI (Lorenz et al., 2002). The above findings may be considered at most suggestive but appear worthy of further study.

The nonhelical mollicutes of the genera *Entomoplasma* and *Mesoplasma* have been found to inhabit the gut of insects (fireflies,

beetles, horseflies, moths, butterflies and bees). However, some entomoplasmas and mesoplasmas have been identified also on plant surfaces, so that most species in either group can be acquired from various plant surfaces or flowers through insect visitation and feeding excursions (Tully, 1996). The current distribution of *Mesoplasma* species, which were initially described as acholeplasmas (Tully et al., 1993), has been summarized in Tully et al. (1994). Again, most isolates have been made from gut fluids of insect hosts, with a few isolations from plant surfaces.

The largest group of mollicutes inhabiting plants is the currently uncultured plant-pathogenic phytoplasmas. These mollicutes are transmitted primarily by phloem-feeding leaf-hoppers and are the causative agents of more than 300 different plant yellows diseases. For a detailed description of the phytoplasma groups, the diseases they cause, their plant hosts, insect vectors, and geographic distribution, see the reviews of Seemuller et al. (2002) and Lee et al. (2000). The different geographic location of any specific phytoplasma depends on the availability of not only the plant host but also the insect vector in the area. Plants infected by phytoplasmas exhibit an array of symptoms that suggest profound disturbances in the normal balance of plant hormones or growth regulators. Symptoms include virescence (green flowers), phyllody (floral parts develop into leafy structures), sterility of flowers, proliferation of auxiliary shoots (witches broom appearance), abnormal elongation of internodes resulting in slender shoots, generalized stunting, discoloration of leaves, and yellowing (Lee et al., 2000; Seemuller et al., 2002).

The phytoplasma vectors belong to the families Cicadelloidae (leafhoppers) and Fulgoroidae (plant hoppers). Some phytoplasmas have low insect vector specificity, whereas others have very high vector specificity. Plant host range for each phytoplasma is largely determined by the number of natural insect vector species capable of transmitting the phytoplasma and by their feeding behavior. Many vectors can transmit more than one type of phytoplasma, and many plants can harbor two or more distinct phytoplasmas. Periwinkle, commonly used as a source plant to maintain phytoplasma cultures, is able to harbor the majority of known phytoplasmas. Overlapping vectors and plant hosts have allowed ample opportunities for phytoplasmas to interact with one another and exchange genetic information. Exchange may occur vertically and horizontally. As a result, a widely diverse phytoplasma group has been formed with characteristics of continual and wide genetic variation among its members (Lee et al., 2000).

Isolation

Several host and cultural factors are important in primary isolation and maintenance of mycoplasmas during early passage levels. These include the chemical and physical suitability of the culture medium, the number of organisms in the tested specimen, and the presence of toxic or inhibitory substances in the inoculum (Tully and Whitcomb, 1992). The use of antibiotics and thallium acetate in culture media has made possible mycoplasma isolation in the presence of a variety of other competing organisms in the tested material. Penicillin (500–1000 units/ml) and polymyxin B (500–1000 units/ml) have been the drugs of choice for inhibition of either Gram-positive or Gram-negative prokaryotes and fungi, respectively (Tully, 1983). Thallium acetate toxicity to man and animals and its possible growth inhibition of some mollicutes, such as ureaplasmas, at the concentration recommended in mycoplasma culture media (about 1 mg/ml) has led to the suggestion (Angulo et al., 2003) that colistin sulfate (37 μg/ml) be used instead. Clearly, the effectiveness of colistin sulfate as a selective agent for mycoplasmas should be tested in clinical diagnostic laboratories prior to replacement of thallium acetate. Mycoplasmas can often be isolated from diluted but not undiluted infected tissue extracts, suggesting that inhibitors like lysolecithin, antimycoplasmal antibodies, and antibiotics are present in host tissues (Taylor-Robinson and Chen, 1983). It is advisable, therefore, to perform serial dilutions of such extracts in fresh culture media in all primary isolation attempts. Early broth passages of newly isolated mycoplasmas are likely to require prolonged incubations rather than the shorter time required for strains well adapted to a particular medium.

The first indication of mycoplasma growth in primary broth cultures is often a slight-to-moderate pH change of the medium, and in most instances, slight turbidity. Phase-contrast and dark-field microscopy may be effective in monitoring broth cultures, particularly in the case of the motile helical spiroplasmas (Tully and Whitcomb, 1992). Checking the agar cultures for the typical fried-egg colonies under a stereomicroscope is the next step. Frequently, the shape of the colonies is not typical. Thus the motile spiroplasmas may form diffuse colonies on the fresh agar surface, lacking the agar-embedded central zone. By increasing the agar concentration, the free water film on the agar surface decreases in thickness (Razin and Oliver, 1961). This impedes spiroplasma motility in the film, resulting in the formation of fried-egg colonies (Tully and Whitcomb, 1992).

Culture Media

A major impediment to mycoplasma research and laboratory diagnosis of mycoplasma infections has been the difficulty of their in vitro cultivation. The consensus is that only a minority of the mycoplasmas existing in nature has been cultivated so far. For example, despite many efforts for over 30 years, none of the phytoplasmas infecting insects and plants has been cultivated in vitro in an axenic culture (Seemuller et al., 2002). Some cultivable mycoplasmas (such as the human respiratory pathogen *M. pneumoniae*) grow very slowly (2–3 weeks incubation at 37°C), particularly on primary isolation. Others, like *Ureaplasma urealyticum*, grow very fast in vitro, but growth stops abruptly at titers of 10^6–10^7 colony-forming units per milliliter (cfu/ml) compared to 10^9–10^{10} cfu/ml in logarithmic-phase cultures of well-growing mycoplasmas (Fig. 13). The recent mycoplasma genome sequencing projects have provided definitive genetic explanations to the above-mentioned difficulties by demonstrating the remarkable scarcity in mycoplasmas of genes involved in biosynthetic pathways. For example, both *M. genitalium* and *M. pneumoniae* lack all the genes involved in amino acid synthesis (Fraser et al., 1995; Himmelreich et al., 1996), making them totally dependent on the exogenous supply of the complete spectrum of amino acids (see Genome Sequencing and Gene Annotation).

To overcome the assimilative deficiencies of the mycoplasmas, complex media are used for their cultivation. The media are usually based on beef heart infusion, peptone, yeast extract and serum with various supplements (see media formulations below). Use of these complex undefined growth media has interfered with the molecular definition of mycoplasmal metabolic pathways, genetic analysis, preparation of mycoplasmal antigens free of serum components, etc. The aim of efforts to replace the serum component was a defined growth medium. Serum has been shown to provide, among other nutrients, fatty acids and cholesterol required for membrane synthesis, in an assimilable, nontoxic form. Serum component substitution by albumin, fatty acids, cholesterol solubilized in Tween 80, or liposomes made of phospholipids and cholesterol, and the addition of serum albumin to neutralize free fatty acid toxicity has met with only limited success (Razin, 1978). Defined culture media were developed for only a few fermentative mycoplasmas. The media contain a complex assortment of amino acids, nucleic acid precursors, lipids, vitamins, inorganic ions, together with glucose as an energy source (Rodwell, 1983; Hackett et al., 1987). Detailed composition of media for mycoplasmas can be found in the section on cultivation and nutrition in *Methods in Mycoplasmology* (Razin and Tully, 1983), in Tully and Whitcomb (1992), Tully (1995a), and in Hackett and Whitcomb (1995).

Composition of some of the more common media for cultivation of mycoplasmas is given below:
Fig. 13. Growth curves of *Ureaplasma urealyticum* compared to that of *Acholeplasma laidlawii*. From Razin (1978).

Modified Hayflick Medium (Freundt, 1983)

Heart infusion broth (Difco)	28.5 g
Deionized water	900 ml
Fresh yeast extract (25%, w/v)	100 ml
Horse serum	200 ml
Calf thymus DNA (0.2%, w/v)	12 ml
Thallium acetate (1%, w/v)	10 ml
Penicillin G (20,000 units/ml)	2.5 ml

Supports good growth of the majority of *Mycoplasma* and *Acholeplasma* species.

Dissolve the heart infusion broth in deionized water and autoclave (121°C for 20 min). Aseptically add the remaining sterile solutions. Adjust final pH to 7.8 with sterile NaOH solution.

Medium SP-4 (Tully, 1995a)

Mycoplasma broth base (Becton-Dickinson, Baltimore, MD)	1.4 g
Tryptone (Difco)	4.0 g
Peptone (Difco)	2.13 g
Deionized water	270 ml
Phenol red solution (0.1% aqueous solution)	8 ml

Use this medium to grow fastidious mycoplasmas and spiroplasmas. Heat to dissolve ingredients and adjust pH to 7.8 (with about 3–4ml of 1N NaOH). Sterilize at 121°C for 20min. For solid medium, add 0.8g of purified agar (Noble, Difco) for each 100-ml volume of broth and omit the phenol red indicator. Add ingredients (below) as sterile supplements. Adjust final pH of the complete medium to 7.6–7.8 and to a final volume of 400ml.

CMRL 1066 tissue culture medium with glutamine (10X, Gibco)	20ml
Glucose (50% aqueous solution)	4ml
Fresh yeast extract (25% aqueous solution, Gibco)	14ml
Yeastolate (4% aqueous solution, Difco)	20ml
Fetal bovine serum (Hyclone Laboratories)	68ml
Penicillin G (100,000 units/ml)	2ml

Heat-inactivate the fetal bovine serum at 56°C for 1h.

For detailed description of the preparation procedure of the SP-4 medium, see Tully (1995a). Additional undefined and defined media for spiroplasma cultivation are described by Tully and Whitcomb (1992) and by Hackett and Whitcomb (1995b).

U9C Urea Medium (Shepard and Lunceford, 1976)

Trypticase soy broth (BBL)	15.0g
Magnesium chloride (MgCl$_2$·6H$_2$O)	0.2g
Yeast extract (Difco)	1.0g
Deionized water	900ml

Supports growth of ureaplasmas and indicates urea hydrolysis. Adjust pH to 5.5 and autoclave at 121°C for 15min. Add aseptically the following sterile solutions.

Urea (10%, w/v)	3ml
L-Cysteine-HCl (2%, w/v)	5ml
GHL tripeptide (Gly-His-Lys, Calbiochem, 20g/ml)	1ml
Horse serum	100ml
Penicillin G (100,000 units/ml)	10ml
Phenol red (1% w/v)	1ml

Adjust the final pH to about 6.0.

The definition of lipid requirements, particularly for cholesterol, has served as an important taxonomic criterion distinguishing the sterol-nonrequiring mollicutes, particularly the *Acholeplasma* species, from the sterol-requiring taxonomic entities. Testing for sterol requirement has been based on the use of a serum-free medium containing serum albumin, fatty acids and various concentrations of cholesterol solubilized in Tween 80, yielding a final Tween concentration of 0.01% (Tully, 1995b). The finding (Rose et al., 1993) that Tween 80 at a final concentration of 0.04% is essential for growth of some of the sterol-nonrequiring mycoplasmas (later named *Mesoplasma* species; Table 1) is still an enigma. It seems unlikely that requirement for this relatively high Tween 80 concentration can be explained by provision of a required fatty acid component, inasmuch as experiments to test this issue by adding a variety of fatty acids have failed.

Although the numerous nutritional requirements of mollicutes dictate the need for complex growth media, the notion that the richer the medium the better, may be wrong. Apparently, at least in some cases, the lack of growth of a mycoplasma in a rich medium is not due to the lack of a specific nutrient but rather to the presence of a component(s) toxic to the mycoplasma. Some *M. hyorhinis* strains, common contaminants of cell cultures, have been known to resist cultivation on conventional mycoplasma media, suggesting that these strains were particularly fastidious. This concept proved to be wrong because these strains could grow well in a minimal serum-free medium. Gardella and Del Guidice (1995) and Del Giudice (1998), therefore, proposed that these "noncultivable" strains are not particularly fastidious but more sensitive to inhibitors found in the complex media, mostly as components of peptone and yeast extract. Hence, "noncultivable" and "fastidious" should be considered as relative terms that take their meaning only in the context of a specific culture system where growth promoters, and possibly inhibitors, are present.

Generally, mollicutes differ markedly in their atmospheric requirements; whereas most mollicutes are facultative anaerobes, and usually favor an anaerobic or low-redox-enhanced CO$_2$ atmosphere on primary isolation, the rumen *Anaeroplasma* and *Asteroleplasma* species are strict anaerobes, very sensitive to oxygen (Table 1). Some mycoplasmas, such as *M. hyorhinis* require an aerobic atmosphere (Gardella and Del Guidice, 1995). The initial pH of the growth medium should be adjusted to about 8.0 for the fermentative mycoplasmas, and to 6.0–6.5 for the nonfermentative arginine-utilizing mycoplasmas and urea-hydrolyzing ureaplasmas. The temperature for mycoplasma growth ranges according to species from about 20–40°C. The optimum temperature for most human and warm-blooded animal mycoplasmas is 36–37°C, while the optimum growth temperature for *M. mobile*, isolated from fish, is 25°C (Kirchhoff et al., 1987) and 30°C for the tortoise mycoplasmas, *M. agassizi* and *M. testudinis* (Brown et al., 2001). Likewise, the optimum temperature for growth of the sterol-requiring entomoplasmas and the sterol-nonrequiring mesoplasmas (isolated from insects and plants) is about 30°C, while the optimum growth temperature of the spiroplasmas and the acholeplasmas is 30–37°C (Tully et al., 1993).

Cocultivation with Cell Cultures

A novel approach to improve the chances of in vitro cultivation of fastidious mollicutes is based

on coculture with eukaryotic cell lines (cell-assisted growth). In this way uncultivable spiroplasmas, such as the Colorado potato beetle spiroplasma (*S. leptinotarsa*) and the *Drosophila* sex-ratio spiroplasma (*S. poulsonii*) were successfully cocultivated first in insect cell lines, and then primary cultures of this spiroplasma were obtained on cell-free media under conditions of low redox, enhanced CO_2 atmosphere, and at a pH lower than 7.0 (for most mollicutes, the initial pH is adjusted to a slightly alkaline value)—the same conditions used in the insect cell cocultures (Hacket and Lynn, 1995; Konai et al., 1996). Though cocultivation of fastidious spiroplasmas with arthropod cell lines has proved itself in these cases, the choice of an adequate medium for primary isolation and subsequent sustained cultivation of these organisms is still much more an art than a science. However, all of the extensive knowledge and techniques that succeeded in primary isolation and cultivation of spiroplasmas have failed so far when applied to cultivation of the plant and insect phytoplasmas.

Cell-assisted cocultivation, using Vero cell cultures, enabled the cultivation of several strains of the highly fastidious human *M. genitalium* from clinical specimens (Jensen et al., 1996). Also in this case, the mycoplasmas grown in cell culture (as was indicated by PCR monitoring) could be subsequently subcultured in a cell-free medium. The above methodology, as complex as it is, requiring heroic efforts, is certainly inadequate for routine cultivation of fastidious mycoplasmas, leaving the door open for the application of molecular techniques, such as PCR, for detection and identification of fastidious, or the so far uncultivable mycoplasmas (see Identification and Taxonomy and Phylogeny).

Identification

Mycoplasma identification and laboratory diagnosis of mycoplasmal infections has been based on the classical bacteriological tests (i.e., morphology, cultural characteristics, physiological and serological properties). Though these tests still play a major role in mycoplasma diagnostics, new tests based on the molecular analysis of genomic DNA, ribosomal RNAs, cell proteins, and lipids appear to have replaced the classical tests (Razin, 2002). In addition, these molecular tests may soon become the prevailing methods for mycoplasma identification. Systematic and detailed description and evaluation of the classical procedures used in mycoplasma identification can be found in the two volumes of *Methods in Mycoplasmology* (Razin and Tully, 1983; Tully and Razin, 1983), whereas the newer molecular methods are included in the two more recent

volumes of *Molecular and Diagnostic Procedures in Mycoplasmology* (Razin and Tully, 1995; Tully and Razin, 1996). See also the concise review of current methods applied to the routine laboratory diagnosis of mycoplasmal infections (Waites et al., 2001).

Cultural Properties and Biochemical Tests

The International Committee on the Taxonomy of Mollicutes (a subcommittee of the International Committee on Systematic Bacteriology) issued recommended tests for mycoplasma identification as well as for description of new species of the class Mollicutes (International Committee, 1995). The recommended tests include those required to define a new isolate at the higher taxonomic levels (class, order and family) as well as tests for genus and species determination. Thus, a test for sterol requirement that depends on growth promotion by cholesterol in the presence of either 0.01% or 0.04% Tween 80 (Tully, 1995b) separates the sterol-nonrequiring *Acholeplasma* and *Mesoplasma* species from the members of Mollicutes that require cholesterol for growth. *Ureaplasma* identification is based on urea hydrolysis tests (Razin, 1983). Other key tests include those for sugar fermentation and arginine hydrolysis (Razin and Tully, 1983).

Serology

A great variety of serological tests have been employed, particularly for mycoplasma species and strain identification. The classical, recommended tests include growth and metabolism inhibition by specific antisera as well as direct and indirect immunofluorescence tests applied to mycoplasma colonies. A combined deformation-metabolism inhibition test system has been used to provide both screening and refined analysis and definition of *Spiroplasma* species (see the relevant chapters in *Methods of Mycoplasmology*; Tully and Razin [1983]). A variety of other, in some cases more sensitive, tests based on principles of enzyme-linked-immunosorbent assay (ELISA), immunobinding, immunoblotting, and immunoperoxidase tests, employing polyclonal or monoclonal antibodies, have been applied to mycoplasma diagnosis (see section B chapters in Tully and Razin [1996]). Owing to their higher sensitivity and specificity, these tests are capable of identifying strains within a species. One particular advantage of the colony immunofluorescence, immunoperoxidase and immunobinding techniques is their ability to distinguish a certain mycoplasma species within a mixed culture, or even on primary isolation plates. However, the finding that many immunodominant antigens

exposed on the mycoplasmal cell surface undergo rapid phase- and size-variation (see the section Antigenic Variation) puts severe restrictions on the use (as a reagent in colony immuno-blotting) of monoclonal antibodies directed to such a variable antigen (Rosengarten and Yogev, 1996). The use of a polyclonal antiserum is, therefore, preferable in these tests.

A great variety of diagnostic procedures based on detection of specific antibodies in sera of humans and animals infected with mycoplasmas have been devised; the procedures as well as the evaluation of the results are discussed in detail in the relevant chapters of *Molecular and Diagnostic Procedures in Mycoplasmology*, volume II (Tully and Razin, 1996) and in Waites et al. (2001).

Serodiagnosis consists of examining serum samples for antibodies that inhibit the growth and metabolism of the organism or form mycoplasmal antigen-antibody complexes that fix complement. The antibody response in mycoplasmal pneumonia is most easily demonstrated by complement fixation, reacting acute- and convalescent-phase sera with intact organisms or their lipid extract as antigen. Development of more defined and specific antigens based on immunodominant *M. pneumoniae* membrane proteins, such as P1 (Gerstenecker and Jacobs, 1993; Tuuminen et al., 2001) or the 116-kDa protein (Duffy et al., 1999) was attempted. A four-fold or greater antibody rise is considered indicative of recent infection, whereas a sustained high antibody titer may not be significant because a relatively high level of antibody may persist for at least 1 year after infection (Daxboeck et al., 2003). A variety of rapid tests based on indirect agglutination of erythrocytes or latex particles coated with *M. pneumoniae* antigens or on an immunofluorescence assay detecting IgM antibodies to *M. pneumoniae* (Dorigo-Zetsma et al., 1999) have been developed, and some are commercially available. A variety of rapid tests based on indirect agglutination of erythrocytes or latex particles coated with *M. pneumoniae* antigens, or an immunofluorescence assay detecting IgM antibodies to *M. pneumoniae* (Dorigo-Zetsma et al., 1999) have been developed, and some are commercially available. Enzyme immunoassay test kits presently represent the largest market share of commercial mycoplasma serologic tests (Suni et al., 2001; Tuuminen et al., 2001; Waites et al., 2001).

In summation, although PCR considerably extends the arsenal of reliable laboratory techniques, serology still retains importance in diagnosis of *M. pneumoniae* infections and of complications associated with *M. pneumoniae* infections. IgM antibodies are frequently diagnostic in children because primary disease is most likely to occur in children. In adults, on the contrary, IgM antibodies alone may not be diagnostic. Serology using IgA and IgA-antibody detection remains the method of choice for the diagnosis of acute infection in adults (Watkins-Riedel et al., 2001). A combination of *M. pneumoniae*-specific PCR in nasopharyngeal aspirates with an IgM-capture immunoassay in acute phase sera increases the sensitivity of laboratory diagnosis of *M. pneumoniae* and provides a laboratory result in only 1–2 days (Ferwerda et al., 2001).

Restriction Endonuclease Analysis

The classic tests for mycoplasma identification and classification have been supplemented by a variety of tests based on genomic DNA analysis. Restriction enzyme analysis of the mycoplasma genome provides a convenient and cost-effective means of determining DNA sequence variations among strains of mollicute species (Razin and Yogev, 1995). The method involves comparison of the number and size of fragments produced by digestion of the chromosomal DNA with a restriction endonuclease that cuts DNA at a fixed position within a specific recognition site, usually composed of 4–6 bp. Because of the high specificity of restriction endonucleases, complete digestion of a given DNA with a specific restriction endonuclease provides a reproducible array of fragments. Separation of the fragments by agarose gel electrophoresis and staining with ethidium bromide provides a restriction pattern that can be compared with that of related strains. Variations in the array of fragments generated by a specific restriction endonuclease are called "restriction fragment length polymorphisms" (RFLPs). These RFLPs can result from sequence rearrangements, insertion or deletion of DNA segments, or from base substitutions within the restriction endonuclease cleavage sites. Restriction endonuclease analysis (REA) has become a most useful taxonomic tool, facilitating the identification and classification of mycoplasmal isolates as well as providing means for evaluating the degree of genotypic heterogeneity of strains within established species (Razin, 1992a, b; Djordjevic et al., 2001). In addition, REA provides valuable information on the type and number of specific nucleotide sequences in the genome, serving as a basis for construction of physical genomic maps. The great advantage of chromosomal REA is that it is universally applicable and sensitive because the entire genome is evaluated for RFLP, and in addition, it is relatively easy to perform. Moreover, unlike sodium dodecyl sulfate (SDS)-PAGE of mycoplasmal cell proteins, REA is not susceptible to contamination by culture medium contaminants, and

requires very little (3–5 µg) of unlabeled DNA per test (Razin and Yogev, 1995).

A more recently developed technique, named "amplified-fragment length polymorphism" (AFLP) is a whole genome fingerprinting method based on the selective amplification of restriction fragments. This multistep procedure combines in an elegant manner the power of PCR with the informativeness of REA. AFLP yields more complex banding patterns than other DNA fingerprinting methods, increasing the discrimination between strains. In this way AFLP can be used as a device in studies of epidemiology, pathogenicity, and genetic variability in natural populations of mollicute species (Koktovic et al., 1999).

Southern blot analysis of genomic DNA (digested by a restriction enzyme and hybridized with a cloned conserved gene or a specific genomic fragment as a probe) has become a most useful tool in the identification, classification and subtyping of mollicutes (Razin, 1992; Yogev and Razin, 1995). The plasmid pMC5, carrying the entire 23S and 5S and most of the 16S rRNA genes of *M. capricolum* (Amikam et al., 1982) was among the first plasmids to be used as probes in Southern blot analysis of mycoplasmal DNA. Because restriction sites and flanking sequences differ within the rRNA operons of various mollicutes (Amikam et al., 1984; Razin et al., 1984), hybridization patterns peculiar to different mollicute species or strains are produced (Figs. 14 and 15). A restriction enzyme having a 6-bp recognition site will usually cut the one or two mycoplasmal rRNA operons in a few sites, so that the hybridization patterns are usually simple and much easier to compare than the multiband restriction patterns obtained by REA of entire genomic DNA. Southern blot hybridization with cloned rRNA genes as probes has been named "ribotyping." However, other conserved genes can be employed as probes, such as the *tuf* gene, encoding the elongation factor EF-Tu. The mollicute genome carries only one copy of this gene, so that the hybridization patterns obtained with restricted mollicute DNAs are also very simple and easy to compare (Razin, 1992).

Polymerase Chain Reaction

The introduction of PCR to diagnostics in the late 1980s pushed aside many of the previously developed DNA probes and commercial kits (Razin, 1994). The PCR tests are several orders of magnitude more sensitive than those based on direct hybridization with a DNA probe. Moreover, PCR is fast, copying a single DNA sequence over a billion times within three hours. Nucleic acid amplification techniques are not

Fig. 15. Hybridization patterns of DNAs from eight *Mycoplasma pneumoniae* strains collected from different epidemics. A) DNAs digested by *Hind*III or by *Eco*RI and hybridized with the rRNA gene probe pMC5. From Yogev et al. (1988a). B) DNAs of the same strains digested by *Cla*I and hybridized with the elongation factor *tufA* gene of *Escherichia coli*. From Yogev et al. (1988c).

Fig. 14. Southern blot hybridization of *Eco* RI-digested DNAs of various mycoplasmas (*Mycoplasma pneumoniae*, *M. genitalium*, *M. gallisepticum*, *Spiroplasma citri*, *M. pirum* and *Acholeplasma laidlawii*) with the rRNA gene probe pMC5, showing hybridization patterns peculiar to the different mollicute species. From Yogev et al. (1989).

limited by the ability of an organism to grow in culture, a feature of paramount importance considering the fastidious nature of the mycoplasmas and the fact that not all mollicutes (notably the phytoplasmas and the hemoplasmas) can be cultured in vitro. Thus, PCR-amplified 16S rDNA subjected to RFLP analysis has become the method of choice for routine detection, differentiation and classification of phytoplasmas (Marcone et al., 2000; Seemuller et al., 2002) and hemoplasmas (see the section Phylogeny and Taxonomy).

Detailed descriptions of methodology and evaluation of PCR-based tests in diagnostics can be found in the relevant chapters of *Molecular and Diagnostic Procedures in Mycoplasmology* (Tully and Razin, 1996b). The first major step in the development of a PCR-based test is the selection of appropriate target sequences for amplification. The sequence to be amplified can be chosen from a published mycoplasmal gene sequence or from a randomly cloned DNA fragment demonstrated to be specific for the detection of the mycoplasma (Caron et al., 2000; Kong et al., 2001). Complete or almost complete sequences of the 16S rRNA genes are now available for almost all the established mollicute species, and can be retrieved from databanks (see the section Phylogeny and Taxonomy). This information enables the selection of a variety of target sequences, starting with sequences in the highly conserved regions of the genes, producing primers of wide specificity (also known as "universal primers"). These primers will react with the DNA of any mycoplasma or even with the DNA of other prokaryotes and may be satisfactory for detection of mycoplasma infection in cell cultures, where the goal is just to screen the cultures for contamination. In case of a need to differentiate between contaminating mycoplasmas, a multiplex PCR system can be employed, consisting of a universal set of primers along with primer sets specific for mycoplasma species commonly infecting cell cultures (Choppa et al., 1998). The mycoplasmal 16S rRNA genes carry in addition to the conserved regions more specific variable regions, as well as specific 16-23S intergenic spacer regions (Tang et al., 2000; Kong et al., 2001). Primers can be selected from these regions with various degrees of specificity, ranging from clusters of species, single species, down to the subspecies level (Kong et al., 2001).

Specimen preparation for PCR testing is an important parameter that should be optimized. Because mycoplasmas have no cell walls, boiling of the sample, following its concentration by centrifugation, is often sufficient to make the organisms' DNA accessible. However, some clinical samples may contain undefined inhibitors of the PCR reaction, reducing the efficiency of amplification, so that DNA extraction has to be employed. Appropriate positive and negative controls should be included in each PCR test to rule out the presence of inhibitory substances. The methodology of target sequence amplification and optimization of the PCR test conditions, as well as the identification of the PCR products by electrophoretic analysis are detailed in De Barbeyrac and Bebear (1996). More recently, colorimetric procedures for identification of specifically amplified double-stranded DNA captured in wells of a microtiter plate were developed. These systems, some of which are commercially available as kits, are cost effective alternatives to gel electrophoresis, particularly for screening of moderately large sample numbers (Bashiruddin et al., 1999).

Although conventional PCR tests should under optimal conditions detect the DNA of a single mycoplasma, this rarely happens in testing clinical material. Two-step (nested) PCR has been devised to increase sensitivity to a level enabling detection of a single mycoplasma in a clinical sample. Another advantage of nested PCR is that the second-round PCR serves to confirm the specificity of the first-round PCR (Harasawa, 1996). Another approach is that termed "Random Amplified Polymorphic DNA (RAPD)," or "Arbitrary Primer PCR (AP-PCR)." It involves PCR amplification with a single arbitrary primer at low stringency, resulting in strain-specific arrays of DNA fragments that can reproducibly distinguish even closely related strains of a species. The simplicity of this procedure and the availability of commercial kits should facilitate the use of RAPD analysis as a routine procedure for identification of strains of a mollicute species, employing the RAPD patterns to investigate disease outbreaks for epidemiologic tracking (Cousin-Allery et al., 2000).

Numerous publications compare the results of the PCR technique with culture and serological testing for *M. pneumoniae* (for references, see Razin [2002] and Daxboeck et al. [2003]). Most publications indicate that PCR yields higher sensitivity and much faster results (for examples, see Ferwerda et al. [2001] and Templeton et al. [2003]). PCR assays can usually detect as little as a few femtograms (fg) of mycoplasmal DNA. When translated into numbers of organisms, 1 fg of mycoplasmal DNA is approximately equivalent to the genomic DNA of a single mycoplasma cell (i.e., about 1000 kb). The ability to detect by PCR a single mycoplasma cell makes PCR the most sensitive detection method available, even more sensitive than culture. In theory, a positive culture can be derived from a single mycoplasma cell. In practice, however, for many reasons

(including mycoplasma cell aggregates, multi-nuclear filamentous forms, and defective or nonviable cells) a positive mycoplasma culture requires an inoculum equivalent to about 100–1000 cells. This is known for other bacteria as well and is the reason for using the expression colony-forming units (cfus) or color-changing units (ccus) rather than number of cells per milliliter (Razin, 1994).

Obviously, PCR should be applied in the case of patients with an impaired immune response where serological tests may be much less effective. Positive PCR results for *M. pneumoniae* in culture-negative persons without evidence of respiratory disease suggests either inadequate specificity of the test, persistence of the organisms after infection, or their existence in asymptomatic carriers, making interpretation of such results difficult (Waites et al., 2001). In other words, does a sensitive technique such as PCR lead to 'over-diagnosis' of *M. pneumoniae* infections and is over-diagnosis partly due to detection of *M. pneumoniae* in healthy carriers? It is still difficult to answer these questions in a definitive manner.

In conclusion, PCR detection of mycoplasmas is still too labor-intensive, expensive and complex to be carried out routinely in most clinical microbiology laboratories. Development of satisfactory commercial PCR kits may simplify the procedures and bring about better standardization of the technique, and if available at a reasonable cost, PCR could become the major method for diagnosis of mycoplasmal infections.

Preservation of Cultures

Cultures of mycoplasmas may retain viability at 4°C for weeks, particularly when glucose is omitted from the medium or when bovine serum albumin and lipids replace serum (Taylor-Robinson and Behnke, 1987). However, prolonged storage of unfrozen cultures is unreliable, so that for long-term preservation, fast freezing of young cultures to –70°C (Raccach et al., 1975) or freeze-drying is recommended. Detailed procedures have been described and evaluated by Leach (1983).

The noncultivability of phytoplasmas so that their identification is based on molecular genetic analyses of their genomic DNA has led to the development of a method using microwave heat treatment of infected plant tissues to preserve phytoplasmal DNA in situ without compromising its stability (Wang and Hiruki, 1998). This treatment offers not only the preservation of phytoplasmal DNA, useful for molecular diagnosis, but also a way for safe international exchange of experimental materials without violating quarantine regulations.

Physiology

The Cell Membrane

MEMBRANE PROTEINS Lacking a cell wall and intracytoplasmic membranes, the mollicutes have only one type of membrane, the plasma membrane. The ease with which this membrane can be isolated and the ability to introduce controlled alterations in its composition have made mycoplasma membranes effective tools in membrane research (Razin, 1978, 1993).

Proteins constitute over two thirds of the mycoplasma membrane mass, the rest being membrane lipids. The structure and function of mycoplasmal membrane proteins have recently been reviewed by Wieslander and Rosen (2002). Membrane lipoproteins have attracted much attention in recent years as their relative abundance in mycoplasma membranes is most remarkable in contrast to the limited number of lipoproteins in membranes of other eubacteria. On the basis of characteristic lipoprotein-specific features, Himmelreich et al. (1996) annotated 46 putative lipoprotein genes in the *M. pneumoniae* genome, while 21 lipoprotein genes have been annotated in the *M. genitalium* genome (Fraser et al., 1995; Himmelreich et al., 1997). The 25 additional lipoprotein genes in *M. pneumoniae* are only gene amplifications, which are frequently organized in sequential order (Herrmann and Reiner, 1998). The *M. pulmonis* genome encodes 56 lipoproteins (Chambaud et al., 2001), while the *U. urealyticum* (*parvum*) genome appears to be the richest, encoding 74 lipoproteins (Glass et al., 2000). The unusually high number of lipoproteins in mollicutes may be attributed to the absence of a cell wall and a periplasmic space in these organisms. Mollicutes possess typical eubacterial signal peptides that direct the newly synthesized proteins into a secretory pathway for transport across the cell membrane (Yogev et al., 1991b). Still, the mollicute lipoprotein signal peptides are longer than for any other bacteria, a feature possibly associated with their thicker cholesterol-containing cell membrane, requiring longer transmembrane segments (Edman et al., 1999).

For surface-exposed membrane proteins which have to function on the cell outside, acylation of the proteins by long chain fatty acids is an effective way of anchoring the proteins to the cell surface. Cultivation of mollicutes (in the presence of labeled palmitate or myristate) labels a significant number of membrane proteins. Interestingly, membrane lipoproteins are

amongst the most dominant antigens in mollicutes (Razin et al., 1998; Wieslander and Rosen, 2002) and a majority of the mycoplasma cell surface antigens known to undergo antigenic variation are lipoproteins (see the section Antigenic Variation). At least some mycoplasmal membrane lipoproteins characterized in *M. pneumoniae*, *M. genitalium*, *M. fermentans* and *M. hyorhinis*, carry only two fatty acid acyl chains linked to the N-terminal cysteine residue via a thioester linkage between diacylglycerol and cysteine, lacking the third fatty acid linked to the amino group of cysteine, normally found in lipoproteins of other eubacteria. In fact, the transacylase responsible for acylation of the amino group of cysteine could not be identified in the *M. pneumoniae* and *M. genitalium* genomic analysis (Himmelreich et al., 1996, 1997; Razin et al., 1998; Calcutt et al., 1999; Le Henaff et al., 2001). Yet, chemical analysis of spiralin (the major lipoprotein of *S. melliferum*) showed that in addition to the two ester-linked acyl chains, a third acyl chain is amide-linked to the cysteine, resembling the classical eubacterial lipoproteins (Le Henaff and Fontenelle, 2000; Le Henaff et al., 2000). Similar findings were reported for the acylated lipoproteins of *M. agalactiae* (Le Henaff et al., 2000).

Molecular genetic methodology has recently enabled the preliminary characterization of membrane proteins of the uncultured phytoplasmas. The phytoplasma membrane proteins characterized thus far are apparently not lipoproteins. They appear to possess cleavable N-terminal signal sequences and a hydrophobic C-terminal anchor. The central hydrophilic domain is located on the outside of the cell membrane (Blomquist et al., 2001; Barbara et al., 2002).

MEMBRANE LIPIDS Virtually all mycoplasma lipids are located in the cell membrane and, as in other biological membranes, consist of phospholipids, glycolipids, and neutral lipids. A detailed description of the composition, distribution and biosynthesis of mycoplasmal membrane lipids can be found in Rottem and Kahane (1993). As mentioned in the Genome Sequencing section, the mycoplasmas are partially or totally incapable of fatty acid synthesis, and they depend on the host (or the culture medium) for their supply. In addition, most mycoplasmas require cholesterol for growth, a unique requirement among prokaryotes (Rottem, 2002b). The fatty acid residues of membrane phospholipids and glycolipids, as well as cholesterol, constitute a major portion of the hydrophobic core of the membrane. The dependence of mycoplasmas on the exogenous supply of fatty acids and cholesterol

has been one of their greatest advantages as models for membrane studies. The ability to introduce controlled alterations in mycoplasma membrane-lipid composition, simply by controlling the composition and content of fatty acids and sterols in the growth medium, has been used most effectively in elucidating the molecular organization and function of the lipids in mycoplasma membranes (Razin, 1993; Wieslander and Rosen, 2002).

Almost all recent studies concerning mycoplasma lipid biosynthesis and its regulation were carried out on *A. laidlawii*, an organism which has been used for a long time as a model organism, particularly in studies dealing with the physical state of the membrane (Razin, 1978, 1993). It has been the organism used by Wieslander, Rilfors, Lindblom and their associates at Umea University to show that altering the polar headgroup structure of membrane phospho- and glycolipids (and changing the acyl chain structure) are the two strategies employed by the organisms to adapt their membrane lipid composition to various environmental and physiological conditions (reviewed by Wieslander and Rosen [2002]). A common way in prokaryotes to respond to varying growth temperatures is to regulate the degree of unsaturation of the acyl chains of the lipids. *Acholeplasma laidlawii* cannot synthesize unsaturated fatty acids and can only synthesize limited amounts of saturated fatty acids when the organism is grown in a thoroughly lipid-depleted medium. Thus, at least one exogenous fatty acid must be supplied in the growth medium for the cells to grow.

Acholeplasma laidlawii exploits a different mechanism to cope with changes in environmental conditions, namely, altering the proportion of lipids with different polar head groups. The Umea group has hypothesized and experimentally supported that *A. laidlawii* strain A-EF22 regulates its membrane lipid composition to maintain a proper balance between lipids forming a lamellar crystalline phase, and lipids forming reversed nonlamellar phases. The first acholeplasmal lipid shown to form a nonlamellar phase was monoglucosyl diacylglycerol (MGlcDAG). The other major glycolipid, diglucosyl diacylglycerol (DGlcDAG), resembles the acholeplasmal phospholipids in forming solely the lamellar phase at all temperatures and with all acyl chain compositions. Then, acholeplasma were found to be capable of varying the proportion of the MGlcDAG and DGlcDAG in response to the prevailing growth conditions (Wieslander and Rosen, 2002).

In conclusion, the extensive studies of the Umea laboratory show that several basic features of the membrane homeostasis mechanism in *A. laidlawii* (including the maintenance of

phase equilibria, spontaneous curvature, and surface charge density of the membrane lipid bilayer) are dependent upon the physical properties of the bilayer. In addition, these features are sensed by the two consecutively acting glucosyltransferases synthesizing the major lipids MGlcDAG and DGlcDAG. Though the fine details of the molecular mechanisms regulating the synthesis of the two glucolipids have to be worked out, the experiments with the purified MGlcDAG synthase suggest that enzyme regulation may depend on the enzyme proteins themselves, not requiring a complex multiprotein regulatory mechanism (Berg et al., 2001; Wieslander and Rosen, 2002).

Metabolism

ENERGY-YIELDING PATHWAYS The small genome size of mollicutes precludes their possession of an extensive range of metabolic activities present in other bacterial groups. Demonstrated metabolic activities appear primarily to be associated with energy generation, rather than with the provision of substrates for synthetic pathways. All the mollicutes so far examined have truncated respiratory systems. They lack a complete tricarboxylic acid (TCA) cycle and have no quinones and cytochromes, ruling out oxidative phosphorylation as an ATP-generating mechanism (Pollack, 2002b). Thus, the demonstrated energy-yielding pathways of mollicutes produce low ATP yields and relatively large quantities of metabolic end products, depleting in some cases host tissues of the specific substrate metabolized.

On the basis of their ability to metabolize carbohydrates, the mollicutes are divided into fermentative and nonfermentative organisms. Members of the fermentative group produce acids from carbohydrates, decreasing the pH of the growth medium. Though fermentative mycoplasmas may differ in their ability to utilize sugars other than glucose, this property has only a limited taxonomic value. Interestingly, *M. fermentans* isolates from the urogenital tract of AIDS patients were found to use fructose in preference to glucose (Ozcan and Miles, 1999). In man, high fructose concentrations relative to glucose are associated only with seminal vesicle secretions. Thus, fructose-utilizing *M. fermentans* strains may be associated particularly with seminal vesicles and their secretions, and be transmitted in semen.

The sequencing projects of the *M. genitalium* and the *M. pneumoniae* genomes (Fraser et al., 1995; Himmelreich et al., 1996) showed that these mycoplasmas carry all the enzymes of the Embden-Meyerhof-Parnas pathway, whereas the second pathway for metabolizing glucose (the pentose phosphate shunt) is incomplete.

Pyruvate generated by glycolysis can be further metabolized either to lactate by lactate dehydrogenase, or to acetyl-CoA by the pyruvate dehydrogenase pathway. Most of the nonfermentative mollicutes, and some fermentative species as well, possess the arginine dihydrolase pathway. Arginine hydrolysis by this pathway results in the production of ornithine, ATP, CO_2 and ammonia, raising the pH of the culture medium (Razin, 1978). The pathway consists of three enzymes: arginine deiminase, ornithine carbamoyl transferase, and carbamate kinase. The degradation of arginine is coupled to equimolar generation of ATP by substrate-level phosphorylation. The role of this pathway as a sole energy-generating source in nonfermentative mollicutes has been frequently questioned (Razin, 1978; Himmelreich et al., 1996, 1997). The demonstration of an arginine-ornithine antiport system in *Spiroplasma melliferum* (requiring no ATP for arginine import into the cells) supports an energetic advantage in arginine utilization (Shirazi et al., 1995), but the question of whether arginine degradation can serve as a sole, or even a major, energy-generating mechanism remains unanswered.

The arginine dihydrolase pathway can be found also in some fermentative *Spiroplasma* and *Mycoplasma* species (see appendix in Tully and Razin [1996]). In this case, when both glucose and arginine are present in the medium, the acids produced by glycolysis would mask the alkalinization caused by the ammonia liberated on arginine degradation, hampering the test for arginine utilization by the simple pH change assay. Yet, as was shown in a nuclear magnetic resonance (^{13}C-NMR) study, the accumulation of lactate and breakdown of arginine by *M. fermentans* were observed in the simultaneous presence of both glucose and arginine, suggesting that glucose utilization has little or no effect on deamination of arginine to citrulline (Olson et al., 1993). Furthermore, proteome analysis of *S. melliferum* showed that the arginine dihydrolase enzyme proteins were constitutively expressed also in the presence of glucose (Cordwell et al., 1997a).

Some mycoplasmas, such as *M. agalactiae*, *M. bovigenitalium* and *M. bovis* (see appendix in Tully and Razin [1996]) metabolize neither sugars nor arginine but can oxidize organic acids (lactate and pyruvate) to acetate and CO_2 (Taylor et al., 1994). The contribution of the oxidation of these substrates to the energy provision of the above mycoplasmas should be worked out. Another potential energy-yielding mechanism in mollicutes is based on ATP generation from acetyl phosphate and adenosine 5′-diphosphate by acetate kinase, coupled with acetyl phosphate formation from acetyl coenzyme A (acetyl-CoA)

by phosphate acetyl transferase; both enzymes are commonly found in fermentative and non-fermentative mollicutes. Acetyl-CoA can be produced by oxidative phosphorylation of pyruvate by mycoplasmas (Razin, 1978). The weight that should be given to this pathway in energy metabolism of mollicutes has not been critically evaluated.

Energy metabolism of ureaplasmas presents a special case. Neither glycolysis nor arginine dihydrolase-ATP- or acetate kinase-ATP-generating pathways could be detected in these organisms. Ureaplasmas are unique among the mollicutes in possessing a very potent urease. Although protein and gene analysis of the ureaplasmal urease complex has shown its subunit structure and composition to resemble the other prokaryotic ureases, the specific activity of the ureaplasmal urease is much higher and was estimated to exceed that of jack bean urease by about 100 fold (Blanchard et al., 1988; Thirkell et al., 1989; Smith et al., 1993). More importantly, ureaplasmas appear to be unique among prokaryotes in requiring urea for growth (Razin, 1978). Thus, the specific urease inhibitor, flurofamide, inhibits ureaplasma growth (Blanchard et al., 1988). The dependence of ureaplasmas on urea for growth has led to the hypothesis that intracellular urea hydrolysis and the resulting intracellular accumulation of ammonia and ammonium ions is coupled to ATP synthesis through a chemiosmotic type of mechanism (Razin, 1978). Experimental support for the generation of a transmembrane potential, with resultant ATP synthesis through the ureaplasmal F_0F_1 ATPase, first provided by Romano et al. (1980), was later extended and confirmed by Smith et al. (1993). At an external pH of 6.0 (the pH optimum for ureaplasma growth in vitro), urea hydrolysis generated an ammonia chemical potential equivalent to almost 80 mV and, simultaneously, an increase in proton electrochemical potential (δp) of about 24 mV with resultant de novo synthesis of ATP (Smith et al., 1993). When the external pH of the growth medium reaches about 8.1, owing to ammonia released from the cells, the intracellular pH rises to 8.6 and urease activity ceases (as shown by pH activity profile of the ureaplasmal urease). Generation of ATP is blocked at this alkaline pH, leading to the abrupt and steep decline of growth, characterizing the ureaplasmal growth curve (Fig. 13). Inhibition of the urease by flurofamide abolished both the chemical potential and the increase of δp, such that ATP synthesis decreased to about 5% of the normally obtained levels (Smith et al., 1993; Glass et al., 2000). Lansoprazole, another specific urease inhibitor, also inhibited ATP synthesis and ureaplasma growth (Nogata et al., 1995). Note that the pH of the urogenital tract is usually on the acid side of neutrality, corresponding to the pH values optimal for ureaplasma growth, maximum increase in δp, maximum ammonia chemical potential, maximum urease activity, and maximum ATP generation.

Resembling other eubacteria, mollicutes possess an F-type ATPase (Razin, 1978). The number and order of genes of the *atp* operon coding for the F_0F_1 ATPase of *M. gallisepticum* (Rasmussen et al., 1992), *M. genitalium* (Fraser et al., 1995) and *M. pneumoniae* (Hilbert et al., 1996) are identical with those of *E. coli* and *Bacillus subtilis*. However, the b subunit (*atpF*) of the mycoplasmal ATPase was found to carry the characteristic features of a lipoprotein (Pyrowolakis et al., 1998). This feature, not known for any other eubacterial ATPase, may explain the long-known inability to detach the mycoplasmal ATPase activity from the cell membrane by varying the osmolarity of the medium or by treating the membrane with EDTA (Razin, 1978).

TRANSPORT The expectation to find in *M. genitalium* and *M. pneumoniae* a proportionally high number of genes involved in transport of the many essential nutrients required for growth has not been substantiated (Fraser et al., 1995; Himmelreich et al., 1996; Paulsen et al., 1998; see the section Genome Sequencing). This has led to the notion that at least some transport systems, such as those for amino acids and oligopeptides, might not be very specific, but little experimental evidence supporting this notion is presently available (Fraser et al., 2000; Pollack, 2002a).

Mycoplasmas, lacking both electron transport and a functional TCA cycle, generate ATP as their primary energy source, and consequently have mostly ATP-dependent permeases, whereas *B. subtilis* generates a proton motive force (*pmf*) as its primary source of energy and accordingly utilizes mostly pmf-dependent carriers (Paulsen et al., 1998). The ABC transporter systems are involved in import or export of a large variety of substrates, including sugars, peptides, proteins and toxins. In fact, the ABC transporters were the most frequent class of proteins found in *B. subtilis* (Kunst et al., 1997) and *E. coli* (Blattner et al., 1997). Generally, bacterial ABC importers have an ATP-binding domain and membrane-spanning domains located on separate polypeptides, whereas the ABC exporters may carry these components on the same or on different polypeptides (Blanchard et al., 1996). The first to show homology of mollicute proteins with ABC transporter systems were Dudler et al. (1988) studying *M. hyorhinis*. Putative ABC transporter genes were reported in *M. hyopneumoniae* (Blanchard et al., 1996), in *U. urealyticum* (*parvum*; Glass et al., 2000), *M. pulmonis* (Cham-

baud et al., 2001) and essentially in all the mollicute genomes sequenced so far; *M. pulmonis* showing the highest number, 56, of genes potentially encoding subunits for ABC transporters. The deduced amino acid sequence of these gene products showed significant homology with the ABC transporter proteins, particularly those of the eukaryotic multidrug resistance (MDR) protein family, a finding previously reported for other bacteria (Paulsen et al., 1998).

Mycoplasma genitalium and *M. pneumoniae* take up amino acids via two amino acid-polyamine choline (APC) transporters, and they probably accumulate peptides and polymers via two distinct ABC-type systems. These four permeases presumably provide the requisite precursors for protein synthesis (Himmelreich et al., 1996; Paulsen et al., 1998). Though trials to identify the substrate-binding domain (OppA) of the ABC oligopeptide transport in *M. genitalium* and *M. pneumoniae* failed (Himmelreich et al., 1996), the more recent study of Henrich et al. (1999) has identified in the homologous ABC transport system of *M. hominis* an OppA that can bind peptides of different length. This flexibility could endow the transporter with a less restrictive substrate specificity.

The highly efficient phosphoenolpyruvate-dependent sugar phosphotransferase transport systems (PTSs) have been reported in mollicutes long ago, and some of their components were partially characterized by classical biochemical methodology (Razin, 1978; Cirillo, 1993). Apparently, *M. genitalium* and *M. pneumoniae* divert a major fraction of their transport capacity to the task of sugar uptake for the purpose of carbon and energy acquisition. Thus, they possess both glucose and fructose phosphotransferase systems, two sugar permeases of the ABC superfamily, and a nonspecific channel protein of the major intrinsic protein (MIP) family, probably capable of transporting small, neutral, straight chain molecules, such as urea, glycerol and various polyols (Paulsen et al., 1998).

The recent molecular genetic approach has enabled a more precise and detailed description of the genes and protein components of the PTS systems (Zhu et al., 1998). Though the *M. genitalium* genome carries the genes for a PTS specific for glucose (Fraser et al., 1995), the closely related *M. pneumoniae* was found to carry two additional PTS systems, one with an apparent specificity for mannitol and another with an unknown specificity (Himmelreich et al., 1996, 1997). Fructose also appears to be imported by the PTS system of *M. pneumoniae*, though Himmelreich et al. (1996) failed to detect in the mycoplasma *fruF*, which is part of the fructose operon in enteric bacteria. Interestingly, the spiroplasmas that have the ability to multiply in insect hosts have, in addition to the glucose and fructose PTS genes, also the genes encoding for the trehalose-PTS enzyme II (trehalose being the major sugar of the insect hemolymph; Andre et al., 2003). A defective PTS system, lacking component E1, was found in *U. urealyticum* (*parvum*) possibly explaining the inability of this mycoplasma to utilize sugars (Glass et al., 2000).

Genetics

Genome Structure

The application of pulse-field gel electrophoresis (PFGE) to mycoplasma genome size determinations (Neimark and Lange, 1990) has provided a much more accurate and labor-saving procedure than the previously used renaturation kinetics method, resulting in a wealth of genome size data. The data show a continuum of genome sizes among mollicutes (less than 600 kb to over 2200 kb) with overlapping values between mollicute genera. Thus, genome sizes of *Mycoplasma* species range from 580 kb for *M. genitalium* to 1380 kb for *M. mycoides* subsp. *mycoides* LC, whereas for the helical *Spiroplasma* species genome size ranges from 780kb for *S. platyhelix* to 2220 kb for *S. ixodetis* (Table 1). The genome size of representative members of 12 major phylogenetic groups of the uncultured phytoplasmas (Marcone et al., 1999) also varied (530–1350 kb), showing considerable size variation within the same phylogenetic group and resembling in this respect the cultured mollicutes. The Bermuda grass white leaf phytoplasma chromosome of 530 kb is not only the smallest mollicute chromosome found to date, but also the smallest chromosome known for any living cell. The size of the *Eperythrozoon suis* genome (reclassified now as a mycoplasma; see the section Phylogeny and Taxonomy) is about 750kb and that of *Haemobartonella felis* (reclassified as *Mycoplasma haemofelis*) is about 1199kb (Berent and Messick, 2003), which is well within the size range of mollicute genomes (Messick et al., 2000).

Clearly, genome size can no longer be taken as the definitive taxonomic criterion, used previously to distinguish higher taxa in Mollicutes (Razin, 1992a, b). Yet, as a general rule, *Acholeplasma* and *Spiroplasma* species, considered phylogenetically as early mollicutes, have larger genome sizes than *Mycoplasma* and *Ureaplasma* species, considered to be phylogenetically more recent (see the sections Phylogeny and Taxonomy). This is in agreement with the notion that Mollicutes have evolved by degenerative or reductive evolution, accompanied by significant losses of genomic sequences (Woese, 1987).

The mycoplasma genome is characteristically low in G+C content. With very few exceptions, the G+C content of mycoplasma genomes is within the range 24–33 mol% (see appendix in Tully and Razin [1996]). The G+C distribution along the genome is uneven. Thus, while the average G+C content of the *M. genitalium* genome is 32 mol%, the G+C content of its rRNA genes is 44 mol%, and of its tRNA genes 52 mol% (Fraser et al., 1995). The *M. pneumoniae* genes for the P1 and ORF6 adhesins, and their repetitive sequences, exhibit a G+C content as high as 56 mol%, though on the other extreme, the origin of replication of this mycoplasma has a G+C content of only 26 mol%. These G+C contents can be compared to 40 mol% of the entire *M. pneumoniae* genome (Himmelreich et al., 1996, 1997). Consequently, many of the mycoplasmal intergenic regions are richer in A+T than the coding regions, reaching values as high as 80–90 mol% (Yogev et al., 1991a; Dybvig and Voelker, 1996). The variable G+C content of coding regions within the mycoplasmal genome has phylogenetic relevance, indicating (in the case of the rRNA and tRNA genes) their highly conserved nature and (in the case of the adhesin genes) their possible exogenous origin (see the section Adhesion to Host Cells).

As in other prokaryotes, some of the adenine and cytosine residues in mycoplasmal genomes may be methylated (Dybvig and Voelker, 1996). In many mycoplasmas, the adenine residues at the GATC site are methylated, but in others, cytosine residues are methylated. Of special interest is the exclusive methylation of the genomic cytosine residues of *S. monobiae* (MQ-1) when they are located 5′ to guanine (CpG), a methylation trait considered unique to eukaryotes (Renbaum et al., 1990).

Extrachromosomal Elements

Among the mollicutes, spiroplasmas and acholeplasmas are most frequently infected by a variety of viruses (phages), whereas very few viruses are known to infect *Mycoplasma* species (Zou et al., 1995; Voelker and Dybvig, 1998). The characteristics of mollicute viruses have been described and discussed in detail previously (Maniloff, 1992; Renaudin, 2002). The mollicute phage DNA genomes (4–40kb) may be either circular or linear, and single- or double-stranded (Dybvig and Voelker, 1996). Of the very few phages infecting *Mycoplasma* species, the most recent phage discovered is the lysogenic phage MAV1, infecting *M. arthritidis* (Voelker and Dybvig, 1999). The finding that this phage is associated with highly arthritogenic strains, and that experimental infection of low-virulence *M. arthritidis*

strains with this phage increases significantly their arthritogenicity, suggest that MAV1 carries a virulence-enhancing factor. Sequencing of the MAV1 linear double-stranded genome (15,644 bp) revealed 15 ORFs (Voelker and Dybvig, 1999). The deduced product of one of the genes, designated "vir," contained a classic prokaryotic lipoprotein signal sequence. If MAV1 encodes in fact a lipoprotein, it may be speculated that this lipoprotein is incorporated into the *M. arthritidis* cell membrane and in this way induces the conversion of the avirulent phenotype into a virulent one (see also the section Pathogenicity).

Plasmids were detected in *S. citri* and in *M. mycoides* subsp. *mycoides* (Dybvig and Voelker, 1996). Extrachromosomal DNA molecules, most prevalent in phytoplasmas of various phylogenetic clades have been postulated to represent plasmids, inasmuch as no virus particles could be observed by electron microscopy (Rekab et al., 1999). The almost universal occurrence of plasmids in phytoplasmas suggests a function for these molecules. The possibility that phytoplasma plasmids may encode genes associated with pathogenicity (Nishigawa et al., 2002) has been raised, but evidence to support this notion is still unavailable. The potential of the mollicute phages and plasmids to serve as cloning and shuttle vectors has been a major reason for interest in these elements (see the section Gene Transfer).

Genome Sequencing and Gene Annotation

Mycoplasmas, carrying the smallest genomes of self-replicating cells, were among the first microorganisms selected for the genome-sequencing projects. The complete sequence of the genome of *M. genitalium* was the second to be reported (Fraser et al., 1995) following closely the report on the complete sequence of the *Haemophilus influenzae* genome (Fleischmann et al., 1995). The remarkable power and cost-effectiveness of the new genome sequencing technology have already resulted in the elucidation of the complete genome sequences (by January 2003) of over 90 eubacteria and archeons (see http://www.tigr.org/tdb/mdb/{the website of The Institute for Genomic Research}). Included among these are the mollicutes *U. urealyticum* (*U. parvum*; Glass et al., 2000), *M. pulmonis* (Chambaud et al., 2001), *M. penetrans* (Sasaki et al., 2002) and *M. gallisepticum* (Papazisi et al., 2003). The genomes of *M. hyopneumoniae*, *M. mycoides* subsp. *mycoides*, and *S. citri* are at advanced or final stages of sequencing. A large part of the *S. kunkelii* genome has been sequenced and annotated (Bai and Hogenhout 2002). Partial sequencing and gene characteriza-

Table 4. Gross properties of sequenced mollicute and *Bacillus subtilis* genomes.

No. of ORFs with no functional prediction or database match	295	230	152	204	453	1,722

Abbreviation: ORF, open reading frame.
Data from Fraser et al. (1995), Himmelreich et al. (1996, 1997), Kunst et al. (1997), Dandekar et al. (2000), Glass et al. (2000), Chambaud et al. (2001), and Sasaki et al. (2002).

tion of a phytoplasmal genome have recently been published (Melamed et al., 2003).

The voluminous genetic data provided by the genomic projects has opened the way for "comparative genomics" by which the total genomic complements of organisms could be compared. This provides an opportunity to explore the functional content of genomes and evolutionary relationships between them at a new qualitative level. Typically, about 40–60% of the genes of a newly sequenced bacterial genome display detectable similarity to protein sequences whose function is at least tentatively known. Gene density is consistent across many bacterial species, with about one gene per kilobase (Fraser et al., 2000). A detailed comparative genomic analysis of *M. genitalium* and its close relative *M. pneumoniae*, compared to that of *H. influenzae* and other eubacteria, was presented in Razin et al. (1998). Table 4 summarizes some of the gross properties of the mollicute genomes sequenced so far, in comparison with the *Bacillus subtilis* genome.

Examination of the mycoplasmal genomic data indicates the biochemical pathways where gene reductions took place, and helps us define the genes that are really essential for a minimal self-replicating cell. In fact, defining the minimal gene set required by a self-replicating cell has become a most attractive research subject, applying *M. genitalium* as a prime candidate for this purpose (Razin et al., 1998; Koonin, 2000; Hutchison and Montague, 2002). Moreover, Hutchison et al. (1999) have promoted the idea of constructing an artificial life form based on the genes found essential for *M. genitalium* survival following global transposon mutagenesis. The essential genes were defined, in part, by the absence of viable mutants containing a transposon insertion within a given coding region. Hutchison et al. identified in this way 243 *M. genitalium* genes whose functions are not essential for cell viability. From this analysis (coupled with statistical and computational analysis), the authors concluded that 265–350 of the 517 genes in *M. genitalium* are essential for its life under

laboratory growth conditions, that is, in the presence of a full complement of essential nutrients and in the absence of environmental stress. Recent announcements in public communication media and in the journals *Nature* (Check, 2002) and *Science* (Zimmer, 2003) indicate that Craig Venter, Hamilton Smith, and Clyde Hutchison have already initiated a most ambitious endeavor directed at the synthesis of an artificial minimal cell. Their idea is to synthesize first an artificial genome, based on the genes found essential for life of *M. genitalium*, and to introduce this synthetic genome into *M. genitalium* cells from which the natural genome was removed. Whether the synthetic genome will hijack the cellular machinery of the genome-depleted host cell is, of course, a great mystery. A most interesting article relevant to the issue of the 'minimal cell' concept is that of Kobayashi et al. (2003). By systematic inactivation of *B. subtilis* genes, they could show that only 271 of the 4112 genes of this bacterium (Table 4) appear essential for its survival and growth under optimal conditions. Again, demonstrating how little genetic information is theoretically needed for the assembly of a minimal cell.

Genomic analysis of *M. genitalium* and *M. pneumoniae* has revealed the scarcity of genes involved in biosynthetic pathways (Fig. 16; for detailed discussion, see Razin et al. [1998] and Dandekar et al. [2002]). The two mycoplasmas have apparently lost during their reductive evolution all the genes involved in amino acid biosynthesis, as well as most of the genes involved in cofactor (vitamin) biosynthesis, so that to cultivate these mycoplasmas in vitro the medium has to be supplemented with the essential amino acids and vitamins. Very significant savings in genetic information have resulted through the loss of the cell wall during mycoplasma evolution. Significant gene savings are also pronounced in lipid metabolism. Most mycoplasmas cannot synthesize any fatty acids and depend, therefore, on the host for their supply (see the section Membrane Lipids). Being deficient in the ability to regulate membrane fluidity by prefer-

ential fatty acid biosynthesis, most mycoplasmas overcome this deficiency by incorporating large quantities of exogenous cholesterol into their membrane. Cholesterol serves as a very effective buffer of membrane fluidity (Razin, 1978). Our early studies on mycoplasma nutrition revealed their requirement for the nucleic acid precursors, purines and pyrimidines. These may be provided by RNA and DNA degraded by the potent mycoplasmal nucleases (Razin, 1978). The present genetic data provide an explanation for these observations by revealing the scarcity in mycoplasmas of genes, and consequently of enzymes, responsible for purine and pyrimidine synthesis, while genes for salvage pathways utilizing purines and pyrimidines for the synthesis of ribonucleotides and their conversion to deoxyribonucleotides have been detected in mycoplasmas (Tham et al. 1993; Fraser et al., 1995; Himmelreich et al., 1996). Notably, the picture of extreme reduction in biosynthetic genes, described above for *M. genitalium* and *M. pneumoniae*, is less pronounced on analysis of larger mollicute genomes. Thus, the 1600kb genome of *S. kunkelii* carries genes for de novo synthesis of several amino acids and nucleosides, as well as regulatory factors not found in *M. genitalium* and *M. pneumoniae* (Bai and Hogenhout, 2002).

The number of genes involved in cellular processes, such as the *fts* genes associated with cell division, heat shock proteins, and genes for chaperones functioning in protein secretion, is definitely smaller in the mycoplasmas as compared to other eubacteria (Fig. 17). However, the major chaperone families HSP70 (DnaK), HSP60 (GroEL), and associated components (e.g.,

DnaJ, GroES, and GrpE) as well as the folding isomerase, and the trigger factor are present in *M. pneumoniae* and *M. genitalium*. In essence, all the constituents of a basic protein folding machinery are present (Bang et al., 2000). Yet, the genes for the chaperonins GroES and GroEL were not detected in *U. urealyticum* (*parvum*) so that different mollicute systems may vary in detail (Glass et al., 2000). The protein secretion system in *M. pneumoniae* is much less complex than in *E. coli*. The channel-forming proteins SecG, SecF, SecE, SecD were not identified in the mycoplasma, leaving only SecA, SecB, SecY, trigger factor, bacterial signal recognition particle, and FtszY as the components of a simplified translocon in *M. pneumoniae* (Himmelreich et al., 1996; Edman et al., 1999; Dandekar et al., 2000).

Many of the regulatory system genes found in other bacteria, such as the two-component signal transduction systems consisting of a sensor and response regulator, were not detected in the two mycoplasmas, but were present in *H. influenzae* (Fig. 17). *Mycoplasma genitalium* and *M. pneumoniae* lack recognizable vestiges of the histidine protein kinases or their target response regulators. Generally, a rough correlation can be observed between genome size and the number of putative protein kinases and protein phosphatases. Thus, while *M. genitalium* carries a single potential protein kinase, *Synechocystis* carries nine potential protein kinases and ten potential protein phosphatases (Shi et al., 1998).

Synechocystis (with its ability to survive on the barest of environmental resources, light and air) presumably has developed and maintained a more extensive cellular sensory, command and control apparatus to support its lifestyle than that of organisms (such as *M. genitalium* and *M. pneumoniae*) specialized to efficiently exploit more monotonous environmental niches (Shi et al., 1998). The *M. penetrans* genome differs from the other mycoplasma genomes sequenced so far (Table 3) by carrying the genes for a predicted two-component signal system (Sasaki et al., 2002). The absence of identifiable transcription factors from *M. genitalium* is most striking. While *E. coli* has 55 known transcriptional activators and 58 repressors, *M. genitalium*, apart from *nusA* and *nusG*, contains only a single transcription elongation factor (Ouzounis et al., 1996), and the *M. pulmonis* genome was found to carry only two transcription regulation factors (Chambaud et al., 2001). Relevant to this issue is the observation that FruR, the product of the *S. citri* gene *fruR*, acts as an activator of the fructose operon transcription in the spiroplasma. This appears to be the first mollicute operon for which regulation of transcription is documented (Gaurivaud et al., 2000c).

The genomes of *M. genitalium*, *M.* pneumoniae, and other mollicutes are deficient in genes coding for components of intermediary and energy metabolism (Fig. 17). Thus, the two mycoplasmas depend mostly on glycolysis as a means for synthesizing ATP. Genes that encode the components of the pyruvate dehydrogenase complex, phosphotransacetylase and acetate kinase, as well as a deficient pentose phosphate pathway were also detected (Fraser et al., 1995; Himmelreich et al., 1996). Most striking is the lack of many energy-yielding systems from the mycoplasmas. No TCA cycle and no quinones and cytochromes were found in any of the mycoplasmas tested (see the sections Energy-Yielding Pathways and Transport). The electron transport system in mycoplasmas is flavin terminated. Thus, ATP is produced in mycoplasmas by substrate-level phosphorylation, a less efficient mechanism than oxidative phosphorylation. In terms of evolution strategy, mollicutes may have concentrated two different functions in a single gene during genome size reduction. This consolidation is evidenced by the malate-lactate dehydrogenase (MDH and LDH) example (Cordwell et al., 1997b) where the gene putatively assigned to lactate dehydrogenase in *M. genitalium* and *M. pneumoniae* fulfills both LDH and MDH functions. A *Spiroplasma citri* gene was also found to encode a bifunctional protein, whose N-terminal domain has a ribosomal function, and the C-terminal domain is involved in inverted repeat sequence (IRS) binding and might have a

regulatory function at the IRS of the genomic DNA (Le Dantec et al., 1998). Along this line, a lipoprotein of *M. hominis* (functioning as an adhesin) was recently shown to function also as the substrate-binding domain OppA of an oligopeptide permease of *M. hominis* (Henrich et al., 1999). The inability to detect in the mollicute genomes sequenced so far the genes for nucleoside-diphosphate reductase and nucleoside diphosphate kinase was surprising, as these are considered indispensable, ubiquitous and highly conserved genes, playing a key role in the synthesis of nucleotide triphosphates. A way out of this problem was proposed by Pollack et al. (2002) suggesting that glycolytic kinases are capable of using a variety of purine and pyrimidine di- and trinucleosides as phosphate donors or acceptors rather than ATP, and in this way supply the required di- and tri-nucleotides.

Being dependent on the exogeous supply of many nutrients would predict the need of mycoplasmas for many transport systems. As can be seen in Fig. 17, the percentage of genes devoted to transport in *M. pneumoniae* and *M. genitalium* is not higher than in *H. influenzae*, though their absolute number is much lower. The small number of transport genes in the two mycoplasmas is even more striking when compared to the 281 transport and binding proteins annotated in *E. coli* K-12 (Blattner et al., 1997) and almost 400 in *B. subtilis* (Kunst et al., 1997). The apparent low substrate specificity of some of the mycoplasmal transport systems, such as those for amino acids (Himmelreich et al., 1996), may contribute to the significant gene saving observed in this category (see the section Transport).

The essential role of the basic processes of DNA replication, transcription and translation, leads to the expectation that saving of genes in these categories will be more restricted as compared to metabolic processes. Figure 18 shows that while the absolute number of genes involved in DNA replication in the mycoplasmas is still much smaller than in *Haemophilus*, the percentage of genes devoted to DNA replication and degradation in *M. genitalium* and *M. pneumoniae* is higher than in *H. influenzae*. This observation points to the essential biological role of these genes, so that evolutionary deletion of genes in this category had to be limited.

Obviously, defining the genes missing from the mycoplasmas is still of interest, as these are apparently of secondary importance. For example, the estimated number of genes functioning in DNA repair in *E. coli* is estimated to be about 100, and approximately 30 in *H. influenzae* (Fraser et al., 1995; Himmelreich et al., 1996; Blattner et al., 1997). Only 13 of the genes known to be involved in excision repair, recombination, and SOS repair of DNA were found

proteins

Fig. 18. DNA replication, transcription and translation genes in the genomes of *Haemophilus influenzae*, *Mycoplasma pneumoniae* and *M. genitalium*. Numbers above the bars indicate the percentages of total putatively identified genes. Based on data from Fleischmann et al. (1995), Fraser et al. (1995), and Himmelreich et al. (1996). From Razin et al. (1998).

genes involved in translation and in ribosome and tRNA synthesis is reflected in their G+C content. Thus, although the overall G+C content of the *M. genitalium* genome is 32 mol%, the G+C of the mycoplasmal rRNA and tRNA genes is 44 mol% and 52 mol%, respectively (Fraser et al., 1995). The degree of homology of the mycoplasmal ribosomal proteins to those of other eubacteria is also very high. Thus, the composition of mycoplasmal translation components resembles very much that of other bacteria. A marked difference can, nevertheless, be observed in the copy number of the rRNA and tRNA genes. Although *E. coli* and *H. influenzae* genomes carry seven and six copies of rRNA operons, respectively, *M. genitalium* and *M. pneumoniae* have only one copy (Table 5). Savings in the number of rRNA genes was long ago shown to be a general property of mycoplasmas, as the maximum copy number of rRNA genes in these organisms is only two, with one exception of three in *Mesoplasma lactucae* (Amikam et al., 1984; Bove, 1993). The number of tRNA genes in mycoplasmas is also kept to a minimum, with very few, if any, gene duplicates (Table 5). Thus, the *M. genitalium* and *M. pneumoniae* genomes carry only 33 genes (Fraser et al., 1995; Himmelreich et al., 1996), and *M. capricolum* carries 30 genes (Muto et al., 1990). These numbers compare with 54 in *H. influenzae* and 86 in *E. coli* (Fleischmann et al., 1995; Fraser et al., 1995; Blattner et al., 1997). Accordingly, the number of anticodons in the mycoplasmas is not much higher than in mitochondria and is close to the essential minimum for translation of all the amino acid codons by wobbling (Razin et al., 1998). Thus, the mycoplasmas appear to possess the minimum machinery needed for protein synthesis. Consequently, protein synthesis and cell replication in mycoplasmas is much slower than in *E. coli*. Thus, the velocity of the DNA replication fork was about 10 times slower in *M. capricolum* than in *E. coli* (Seto and Miyata, 1998). Yet, mycoplasmas appear to grow well in the protective and constant environment of their host and a slow replication rate cannot really be considered as a deficiency of a parasite that can only lose by killing its host. In fact, mycoplasma infections are usually rather mild and chronic in nature (see the section Pathogenicity).

There can be little doubt that the considerable gene number reduction depends primarily on the obligate parasitic lifestyle of mycoplasmas. Some genomic price has to be paid for parasitism; that is, mycoplasma cells must possess surface components enabling their attachment to the host cells. In some cases, including *M. genitalium* and *M. pneumoniae*, the mycoplasmas developed special attachment organelles. Obviously, significant numbers of genes are involved

by Himmelreich et al. (1996) in *M. pneumoniae*. Presumably, those genes detected in the mycoplasmas, including the uracil DNA glycosylase gene, the ABC excinuclease genes, and *recA*, must represent the genes really essential for DNA repair (see the section DNA Replication and Repair).

As to transcription, the percentage of genes devoted to transcription also is higher in the mycoplasmas than in *Haemophilus*, though their absolute number is definitely smaller in the mycoplasma (Fig. 18). Included in this category are the genes for the RNA polymerase subunits, which are basically similar in mycoplasma and the other eubacteria (see the section Transcription), and the genes for RNA helicases. The two mycoplasmas encode only a single σ factor, compared to at least 6 in *E. coli* (Blattner et al., 1997) and 18 in *B. subtilis* (Kunst et al., 1997). The *M. genitalium* genome carries only 2 ribonuclease genes, compared to 10 in *H. influenzae* (Fraser et al., 1995; Himmelreich et al., 1996).

The translation and protein synthesis machinery constitutes apparently the most conserved system in eubacteria, indicating that it represents a very efficient and successful evolutionary development. The highly conserved nature of the

in construction of such an organelle (Balish and Krause, 2002). Some of these genes have already been identified and characterized (see the section Adhesion to Host Cells), but some have not and are apparently included in an as yet unidentified part of the mycoplasmal coding regions or genes.

TRANSCRIPTOMES AND PROTEOMES Experimental identification and confirmation of the proposed gene products at the cellular level has become complementary to identification by sequence comparison. Gene expression can be studied either at the level of transcription or at the level of translation. When these analyses are carried out on intact cells, the terms "transcriptome" (defined as the sum of all transcripts derived from a genome) and "proteome" (the expressed total protein complement of a genome) apply.

Transcriptome analysis uses microarray technology to determine expression level of thousands of genes all at once (Weiner et al., 2002a). For this purpose total RNA is isolated from the mycoplasma grown under defined laboratory conditions. The RNA is transcribed into a single-stranded complementary DNA and is labeled with [33]P. Specific probes are synthesized for all proposed ORFs by PCR, and the probes are immobilized on nylon membranes and tested for cross-hybridization with the labeled cDNA. This technique was used to analyze gene expression in *M. pneumoniae* grown under various conditions, such as heat shock, oxidative stress, and growth in the presence of different antibiotics (Weiner et al., 2000, 2002, 2003). Of the 688 proposed *M. pneumoniae* genes, about 600 were transcribed, but transcription of many genes was temperature dependent and therefore regulated, while numerous genes were constitutively expressed at all temperatures. Interestingly, a substantial proportion of genes with high transcription signals had no known function. Yet, their high expression level suggests that they code for important products (Weiner et al., 2002).

Proteome analysis involves 2D-gel electrophoresis for the separation of proteins according to isoelectric point (pI) and molecular mass, knowledge of the sequences of all cell proteins, and mass spectrometry for the characterization of individual proteins. The combination of peptide mass fingerprinting and peptide fragmentation (which matches the masses of in-gel proteolytically generated peptides against theoretically digested proteins from the database) has proven to be very effective and reliable (Regula et al., 2000; Weiner et al., 2002; Ueberle et al., 2002).

Mycoplasmas are particularly suitable for proteome analysis, as a high percentage of their proteins can be visualized by 2D-gel electrophoresis, analyzed and identified. Moreover, the highly conserved nature of a large part of mycoplasmal proteins facilitates their identification. The major limitations of the proteome approach are: 1) Not all cell proteins are expressed at a given time. Thus, visualizing an entire proteome under a specific set of experimental conditions is improbable. 2) The detection threshold of 2D-PAGE is a limiting factor, as a low copy number of protein molecules may not be detected. 3) Proteins with an isoelectric point higher than 11 cannot be separated well in the first dimension of immobilized pH gradients as well as proteins with 5 or more transmembrane segments. 4) Presently, proteome analysis is only useful for identifying proteins for which the DNA sequence of their genes is available. 5) Co- and posttranslational modification of proteins may increase the number of protein spots per gene (Ueberle et al., 2002).

The pioneering work on mollicute proteome analysis was carried out by Humphery-Smith and his colleagues on *Spiroplasma melliferum* (Cordwell et al., 1997a) and on *M. genitalium* (Wasinger et al., 1995) at a time when complete genome sequences were not available and the sensitivity and accuracy of mass spectrometry methods were inferior to those of today. In a more recent study, Wasinger et al. (2000) could resolve 427 protein spots in proteome analysis of exponentially grown *M. genitalium* cells. Of the 201 proteins of sufficient abundance, 158 could be identified by peptide mass fingerprinting. A reduction of 42% in protein spots was noticed in postexponentially grown cells. On the whole, only about one-third of the proteins in the predicted *M. genitalium* proteome could be identified by them. Proteome analysis of *M. pneumoniae* by Regula et al. (2000) characterized about 350 protein spots. These 350 proteins could be assigned to 224 genes. Clearly, the *M. pneumoniae* proteome map is still far from being as complete as that of *M. genitalium*. Ueberle et al. (2002) concluded that because of the technical problems discussed above, a complete proteome analysis based on the separation of cell proteins by 2D-gel electrophoresis cannot be achieved at the present, even for simple organisms like *M. genitalium* and *M. pneumoniae*.

DNA Replication and Repair

The recent mycoplasma genome sequencing projects, as well as the study of Barnes et al. (1994) on *M. pulmonis* DNA polymerases, have clarified considerably the nature of the mycoplasmal DNA polymerases. Apparently, the mycoplasmas carry the central enzyme for DNA replication—the DNA polymerase III holoenzyme (Pol III) that has the essential characteristics of the eubacterial Gram-positive Pol III. Although the genes responsible for building the major subunits of the holoenzyme, such as the α (*dnaE* or *polC*) and β subunits (*dnaN*) were detected, several other genes responsible for other subunits were missing from the *M. genitalium* and *M. pneumoniae* genomic analysis (Fraser et al., 1995; Himmelreich et al., 1996), indicating a simplified DNA replication complex in the mycoplasmas compared with that of *E. coli* or *H. influenzae*. Yet, most importantly, the mycoplasmal Pol III α-subunit (about 1400 amino acids) included the motif for 3′→5′ exonuclease activity typical for Pol C of Gram-positive bacteria (Barnes et al., 1994; Himmelreich et al., 1996; Kunst et al., 1997), providing an answer to the question of how DNA proofreading is done in mycoplasmas.

Barnes et al. (1994) presented experimental evidence for a second enzyme with DNA polymerase activity in *M. pulmonis*. This correlates with sequence data for *M. genitalium* and *M. pneumoniae*, indicating that at least these three *Mycoplasma* species carry two DNA polymerase genes. One codes for the larger protein (about 166kDa) with a 3′→5′ exonuclease activity and high sequence similarity to the *B. subtilis* polymerase III. The other gene codes for a Pol III homologue (about 100kDa) resembling more the *polC* gene from *E. coli* and lacking a 3′→5′ exonuclease domain. This smaller enzyme may correspond to the DNA polymerases lacking exonuclease activity isolated earlier from *M. orale* and *M. hyorhinis* (reviewed in Maurel et al. [1989]). The picture appears different for the recently sequenced genome of *Spiroplasma kunkelii* where its larger genome carries a *polA* gene that may encode the full length DNA polymerase I protein, including the proofreading and Klenow domains, resembling in this respect *Streptococcus pneumoniae* (Bai and Hogenhout, 2002).

Notably, though the major components of the DNA polymerase machinery are present in *M. genitalium* and *M. pneumoniae*, their genetic maps reveal the absence of many genes (including some major ones) involved in DNA replication (e.g., initiation, elongation, and termination of replication; Fig. 18). Most puzzling was the early failure to detect RNase H in the *M. genitalium* and *M. pneumoniae* genomes. This enzyme cleaves RNA in RNA-DNA hybrid molecules and is thought to be present in all living organisms. More recent reanalysis of the genomic data by Bellgard and Gojobori (1999) has identified new ORFs in both genomes. The most significant identification was that of RNase H, indicating the need for detailed reanalysis of genomic sequences by a more robust systematic approach for ORF identification.

Topoisomerases (topos) catalyze the interconversions of topological isomers of DNA molecules, fulfilling an essential role in DNA replication, transcription, recombination and repair. The mycoplasmal DNA topos, characterized so far, are the DNA gyrase and topoisomerase IV, both belonging to type II topos. Both mycoplasmal enzymes resemble their eubacterial counterparts in having a tetrameric structure composed of two subunits: A and B in the case of DNA gyrase, and the products of *parC* and *parE* genes in the case of topoisomerase IV (Ladefoged and Christiansen, 1994; Bebear et al., 1998a). The DNA gyrase introduces negative supercoils into a relaxed closed circular DNA molecule in a reaction requiring ATP. Interest in the molecular characterization of mycoplasmal topoisomerases has been boosted by the fact that these enzymes are the targets of fluoroquinolones, among the most

effective antimycoplasmal drugs (Kenny et al., 1999; Bebear and Bebear, 2002; Reinhardt et al., 2002; Bebear et al., 2003).

The three genes coding for the ABC excinucleases are present in *M. genitalium*, *M. pneumoniae* and *M. capricolum* so that together with Pol I, helicase II and ligase should provide the mechanism for repair of ultraviolet (UV) damage, such as crosslinking. While dark reactivation of UV damage (excision repair) operates in the above mycoplasmas, photoreactivation may be missing, as the photolyase (*phr*) gene could not be identified in *M. genitalium* and *M. pneumoniae*. The RecA protein plays a central role in recombination-repair, homologous recombination, and initiation of the SOS response. The *recA* gene has been found essentially in all the mollicutes analyzed so far (Zou and Dybvig, 2002). Surprisingly, *S. citri* R8A2 was found to lack a significant portion of the N-terminus of RecA (Marais et al., 1996) affecting its function. However, truncation of RecA is not a characteristic of other *Spiroplasma* species, such as *S. melliferum* (Cordwell et al., 1997a; Melcher and Fletcher, 1999). Not surprisingly, searching of DNA repair systems in mollicutes has been associated with the high mutation rates and high tempo of evolution in Mollicutes (Rocha and Blanchard, 2002). For an in-depth treatment of the issue of DNA replication and repair in mycoplasmas, the reader is referred to Zou and Dybvig (2002).

Transcription and Translation

The DNA-dependent RNA polymerase of mollicutes resembles in subunit structure that of other eubacteria. Thus, the core RNA polymerase of *M. genitalium* (Fraser et al., 1995) and *M. pneumoniae* (Himmelreich et al., 1996) is coded by the conserved genes *rpoA* α subunit, *rpoB* β subunit and *rpoC* β′ subunit. One of the peculiar properties of mollicutes is their resistance to the antibiotics rifamycin and streptolydigin (Bove, 1993; Table 5). Cloning and sequencing of the *rpoB* gene from *S. citri* (Gaurivaud et al., 1996; Laigret et al., 1996) and *M. gallisepticum* suggest that minor differences in amino acid sequences in the β-subunit Rif region, the region responsible for rifamycin binding, may confer rifamycin resistance.

Modulation of promoter selectivity of RNA polymerase by replacement of the σ subunits is an efficient way to alter the global pattern of gene expression in response to changes in environmental conditions. Thus, the *E. coli* genome carries at least 6 σ factors, and that of *B. subtilis*, 18 (Kunst et al., 1997). The presence of only one σ factor in the mycoplasmas (Himmelreich et al., 1996) suggests that the response to external stimuli in these organisms is not controlled by the level of expression of alternative σ factors. Mycoplasmas have conserved the heat shock response, and heat shock proteins (resembling the eubacterial DnaK [HSP70] and GroEL proteins) have been identified in several mollicutes. The *M. genitalium* and *M. pneumoniae* genomes carry genes for seven heat shock proteins (Fraser et al., 1995; Himmelreich et al., 1996). Almost as striking as the absence of a cell wall in these mycoplasmas is their lack of alternative σ factors, two-component signal transduction systems, or other means of gene regulation common to prototypical walled bacteria.

TRANSCRIPTION SIGNALS The mycoplasmal transcription signals resemble generally the classical eubacterial ones. The mycoplasmal –10 (Pribnow box) and to a lesser extent the –35 regions (consensus sequences) resemble the eubacterial promoter consensus sequences recognized by the RNA polymerase holoenzyme (Weiner et al., 2000). A consensus Shine-Dalgarno (SD) sequence could also be identified upstream to the initiation codon (Bove, 1993; Dybvig and Voelker, 1996) though in many cases the SD sequence could not be identified, indicating that signals other than the SD sequence may function as a ribosomal binding site for some mollicute genes. Termination of transcription in mollicutes appears to be independent of the termination factor Rho, as its gene could not be detected in the mycoplasmal genomes analyzed thus far.

RIBOSOMAL PROTEINS AND RIBOSOMAL RNAS The translation machinery of mycoplasmas is rather comprehensive. In *M. pneumoniae* and *M. genitalium*, it is comprised of 99 proposed genes, constituting about 15–20% of the genome's ORFs (Fig. 18). The mycoplasmal ribosomes are typically prokaryotic in size, shape and composition. The *M. pneumoniae* ribosomal protein genes are organized in operons, retaining some of the gene order found in the *E. coli* and *B. subtilis* genomes (Hilbert et al., 1996). Of the 50 ribosomal proteins found in *E. coli*, only the gene for protein S1 could not be detected in *M. genitalium* and *M. pneumoniae*, resembling in this respect a number of Gram-positive bacteria, including *Bacillus* (Fraser et al., 1995; Himmelreich et al., 1996). The highly conserved nature of the ribosomal protein genes has also found its use in establishing mollicute phylogeny (see the section Phylogeny and Taxonomy).

Organization of the mollicute rRNA genes generally follows the characteristic eubacterial order: 16S-23S-5S, functioning as an operon (Glaser et al., 1992). Some exceptions to the above classical rRNA gene organization have

been reported (Razin et al., 1998; Chambaud et al., 2001). Mollicute genomes carry only one or two rRNA gene sets (Table 5), whereas *Clostridium ramosum* and *Clostridium innocuum*, phylogenetically closest to mollicutes, have four and five sets of rRNA genes, respectively (Bove, 1993). Interestingly, phytoplasmas carry two rRNA gene sets, resembling in this respect their phylogenetic relatives, the acholeplasmas (see the section Phylogeny and Taxonomy).

Transfer Rnas The number of tRNA genes in mollicutes is kept to a minimum, with very few gene duplicates (Table 5). The set of 29 tRNA genes identified in the *M. pulmonis* genome represents the smallest set of tRNA genes among the sequenced genomes (Chambaud et al., 2001). Accordingly, the number of anticodons in the mycoplasmas is not much higher than in mitochondria and is close to the essential minimum for translation of all the amino acid codons by wobbling (Muto and Ushida, 2002).

Codon Usage Most mollicutes have genomes with a very low G+C content (Table 1), the outcome of an AT-biased directional mutation pressure (A-T pressure) during their evolution (Muto and Ushida, 2002). This has resulted in codon usage favoring synonymous codons with A and T, particularly in the wobble (3′) position. Codon bias in the AT-rich mycoplasmas is not limited to the third nucleotide position and is evident also in the first and second positions. Mycoplasmas have fewer GGN, CCN, GCN and CGN codons.

Another apparent outcome of codon reassignment under strong A-T pressure is the reassignment in most mollicutes of UGA from a stop codon to a tryptophan codon, a feature found in mitochondria (Osawa et al., 1992). As can be seen in Table 5, not all mollicutes share this property. The phylogenetically early acholeplasmas and phytoplasmas (see the section Phylogeny and Taxonomy) use the conventional UGG codon for tryptophan, carry tRNA^Trp (CCA), and retain UGA as a stop codon. As a consequence of using UGA as a tryptophan codon, it is difficult to express cloned mollicute genes in *E. coli*. Because *E. coli* regards UGA as a stop codon, translation of a mycoplasmal message in *E. coli* will stop where originally there should be tryptophan, so that mycoplasmal proteins expressed in *E. coli* may be truncated. One way to overcome this difficulty is by using an *E. coli* opal suppressor strain for expression (Renbaum et al., 1990; Smiley and Minion, 1993), though efficiency of expression falls considerably with increasing numbers of UGAs in the mycoplasmal message. Another way is to employ *Bacillus subtilis* that carries a tRNA that reads the UGA

termination codon as tryptophan (Kannan and Baseman, 2000).

In mitochondria, family codon boxes are each read by a single tRNA having an unmodified uridine at the first (or wobble) position of the anticodon. Similarly, *M. capricolum* and *M. mycoides* carry only a single isoacceptor tRNA for six of the eight family boxes (Andachi et al., 1989; Inagaki et al., 1995), and *M. pneumoniae* carries a single tRNA for each of the Ala, Leu, Pro and Val family boxes (Simoneau et al., 1993).

The elongation factor genes (*fus*, *efp*, *tsf* and *tuf*) were identified in the *M. genitalium* and *M. pneumoniae* genomes (Fraser et al., 1995; Himmelreich et al., 1996). Of these, the *tuf* gene, encoding the elongation factor EF-Tu, which mediates attachment of amino acyl-tRNAs to the ribosome, has attracted the most attention. It has been one of the first mollicute genes to be cloned, sequenced and expressed in *E. coli* (Yogev et al., 1990; Luneberg et al., 1991). Being a highly conserved housekeeping gene found in all mollicutes examined so far, it has been used as an effective genetic probe in taxonomy and phylogeny of mollicutes (see the section Phylogeny and Taxonomy). Of phylogenetic interest is the finding by Berg and Seemuller (1999a) that in the phytoplasma chromosome, the *fus* and *tuf* genes are linked in a transcriptional unit (the *str* operon) including also the ribosomal protein genes, *rps 12* and *rps 7*, resembling the chromosomal arrangement in *B. subtilis*. In members of the *Mycoplasma* genus, the *tuf* and *fus* genes are found in a different locus and are separately transcribed. This finding strengthens the notion that phytoplasmas are more closely related than the genus *Mycoplasma* is to the ancestral *Lactobacillus* group (see the section Phylogeny and Taxonomy).

Gene Transfer

The lack of a cell wall in mollicutes would be expected to facilitate the introduction of exogenous DNA into the cells. In fact, the exchange of chromosomal DNA during direct contact of mycoplasma cells (Barroso and Labarere, 1988) and conjugative transposition of transposon Tn*916* from *Streptococcus* (*Enterococcus*) *faecalis* to *M. hominis* (Roberts and Kenny, 1987) and to *M. gallisepticum* (Ruffin et al., 2000) by a spontaneous mating process, probably involves transient fusion of the cell membranes at the zone of contact. However, DNA transfer efficiency in these cases was rather low. Increased transformation and transfection efficiencies have been achieved either in the presence of polyethylene glycol (PEG) or by application of the electroporation procedure. Apparently, the method of choice depends on the mollicute species, and

on the particular DNA to be transferred (Dybvig and Voelker, 1996).

Genetic studies in mollicutes also have been hampered by the paucity of selectable markers (Dybvig and Voelker, 1996). Most studies on gene transfer in mollicutes have used as selectable markers the *tetM* tetracycline-resistance determinant found on Tn*916*, or the gentamycin-resistance determinant of Tn*4001*. The *tetM* gene is preferable as a marker because mollicutes in general are sensitive to tetracycline, whereas not all mollicutes are sensitive to gentamycin (Dybvig and Voelker, 1996). Thus, transposon Tn*4001* containing the *tetM* gene constructed by Dybvig et al. (2000) was found effective as a broad host-range vector, as indicated by the successful expression of a *lacZ* fusion gene in both *M. pulmonis* and *M. arthritidis*.

Gene function can be ascertained only by mutational analysis. The recent deluge of information on putatively identified mycoplasmal genes, based on sequence analysis (see the section Genome Sequencing and Gene Annotation), has emphasized the need for complementation of these predictions by mutational analysis. Having efficient transformation procedures at hand, major efforts have been directed at developing cloning and shuttle vectors for mollicutes (reviewed by Renaudin [2002]). Transfection experiments with the replicative form (RF) of the *S. citri* virus SpV1, carrying as an insert a segment of the gene coding for the P1 adhesin of *M. pneumoniae* (G-fragment) resulted in the expression of the fragment in the spiroplasma. In this case, the presence of seven UGA codons in the G-fragment insert did not interfere with expression, as *S. citri* can read UGA as tryptophan (Marais et al., 1993). Yet, the SpV1-RF/*S. citri* cloning system was deficient insofar as it suffered from the rapid loss of the cloned DNA insert. The loss of the insert was suggested to be the result of illegitimate and homologous recombination (Marais et al., 1993). An improved type of a cloning vector for *S. citri* was subsequently constructed by combining the *oriC* of *S. citri* with *tetM* and a colE1-derived *E. coli* replicon. The artificial recombinant plasmid, named "pBOT1," was able to replicate in *S. citri* and then integrate into the spiroplasmal chromosome, being stably maintained there (Renaudin, 2002). The pBOT1-derived, recombinant plasmids carrying heterologous DNA inserts were effective as shuttle vectors and, for example, restored fructose utilization in a mutant with a defective fructose operon (Gaurivaud et al., 2000a). Furthermore, similar *oriC* plasmids, developed for three mycoplasmas belonging to the *M. mycoides* cluster, showed that host specificity of these plasmids is not absolute, and closely related mollicutes exhibit a variable ability to replicate heterologous plasmids (Lartigue et al., 2003), indicating that *oriC*-based plasmids may serve as effective genetic vectors in mollicutes.

TRANSPOSITION The first successful transformation of *M. pulmonis* and *A. laidlawii* to antibiotic resistance was achieved by a plasmid, pAM120, harboring the streptococcal transposon Tn*916*, which contains the tetracycline-resistance determinant *tetM* (Dybvig and Cassell, 1987). The transposon was excised from the plasmid and integrated into the mycoplasmal chromosome at random sites, rendering the mycoplasmas resistant to tetracycline. Since then, a variety of mollicute species were shown to be transformed to tetracycline resistance by Tn*916* or Tn*1545*, or to gentamycin resistance, using the staphylococcal conjugative transposon Tn*4001*, which contains a gentamycin-resistance determinant (Voelker and Dybvig, 1996; Foissac et al., 1997a).

Transposon mutagenesis has already been applied rather effectively to generate mutants of *M. pneumoniae* and *M. genitalium* deficient in cytadherence (Krause et al., 1997) and of *S. citri* mutants deficient in motility and pathogenicity to plants (Foissac et al., 1997b; Jacob et al., 1997). Characterization of these mutants has already contributed significantly to the identification of genes and their protein products, associated with the mycoplasmal cytoskeleton and cytadherence (see the section Adhesion to Host Cells), spiroplasmal motility (see the section Morphology and Motility), and pathogenicity (see the section Pathogenicity). Doubtless, transposon mutagenesis will continue to be a most useful tool in mollicute genomic studies.

Though transposon mutagenesis is either random or directed to specific hot spots in the mycoplasmal genome, Dhandayuthapani et al. (1999) have introduced a technology enabling the targeting of mutagenesis to specific genes or operons. The technique is based on creation and delivery of disruption constructs acting by homologous recombination. The constructed plasmids contain the targeted gene and a gentamycin-resistance gene. Electroporation of the disruption plasmid, carrying part of the *mg218 M. genitalium* gene into wildtype hemagglutination-positive *M. genitalium*, permitted the isolation of hemagglutination-negative mutants, resulting apparently from homologous recombination at the *mg218* locus by single- or double-crossover events. In this way the role of the mg218 protein product in *M. genitalium* adherence could be demonstrated.

RESTRICTION AND MODIFICATION Restriction and modification of DNA allow a bacterium to distinguish between its own DNA and any foreign

DNA that lacks the characteristic host modification pattern. This difference renders an invading foreign DNA susceptible to attack by restriction enzymes that recognize the absence of methyl groups at the appropriate sites. Hence, these systems may pose a serious barrier to gene transfer. Restriction and modification systems in mollicutes have been recently reviewed by Sitaraman and Dybvig (2002). Generally, the restriction-modification (R-M) systems characterized in mollicutes in the past were defined as type II R-M systems, in which the endonuclease is separate from the methylase. More recently, *M. pulmonis* was found to possess a more complex type I R-M system, built of the S, M and R subunits. These subunits form a holoenzyme that performs both the endonuclease and DNA methylase activities (Dybvig et al., 1998).

CHROMOSOMAL REARRANGEMENTS The mollicute chromosome is a genetically dynamic structure undergoing frequent rearrangements, insertions, deletions, and inversions of genes or entire genomic segments. The mollicute genome may carry repetitive elements of various types, such as insertion sequence-like elements (ISLEs; see below), integrated viral or plasmid genomic segments, or repetitive elements of endogenous origin, constituting segments of mycoplasmal genes, as well as recombinases recently identified in mycoplasma genomes (Glew et al., 2002; Sitaraman et al., 2002; Flitman-Tene et al., 2003). These are the elements, which facilitate, through homologous recombination, chromosomal rearrangements as well as loss of genomic material by deletion of intervening sequences during recombination, a process presumably taking place during the reductive evolution of mollicutes (Rocha and Blanchard, 2002). The various types and mechanisms of chromosomal gene rearrangements in mycoplasmas have been extensively reviewed by Sitaraman and Dybvig (2002). Chromosomal rearrangements that play a crucial role in antigenic variation are discussed in the section Antigenic Variation.

INSERTION SEQUENCE-LIKE ELEMENTS Repetitive elements resembling the large insertion sequence (IS)*3* family of bacterial insertion sequences appear to be rather prevalent in mollicutes (Razin et al., 1998). However, of these, only IS*1138* was shown to actively transpose in *M. pulmonis* (Bhugra and Dybvig, 1993), whereas all the other elements that failed to show transposition within the mycoplasma chromosome are usually referred to as "IS-like elements" or ISLEs. The *M. pulmonis* IS*1138* is the only mycoplasmal ISLE shown to transpose in

the *M. pulmonis* chromosome at high frequency. The predicted amino acids encoded by the major IS*1138* ORF share significant similarity with the transposases of the IS*3* family, suggesting that IS*1138* has a potential for development into a cloning vector and mutagenesis vehicle in *M. pulmonis*. Notably, IS*1138* is species-specific to *M. pulmonis*, but it is ubiquitous among its strains (Bhugra and Dybvig, 1993).

Another species-specific ISLE is IS*1634*. It was recently identified in *M. mycoides* subsp. *mycoides* (small-colony type) and belongs to the IS*4* family. This pathogenic mycoplasma is distinguished by its exceptionally high number of insertion elements. Its genome was found to carry about 30 copies of IS*1634*, and about 20 copies of another, less specific IS*1296* element, comprising together about 7% of the total genomic DNA (Vilei et al., 1999). One may speculate that the numerous copies of these elements play a role in regulating the expression of the organism's genetic potential, including invasion ability into host tissues, characterizing this highly virulent mycoplasma (Vilei et al., 1999). A new type of an IS element, named "IS*1630*," was discovered in *M. fermentans* by Calcutt et al. (1999b). It belongs to the IS*30* family of transposons and has the striking ability to target and duplicate inverted repeats of variable length and sequence during transposition. In addition, the IS elements may influence gene expression, either by directly inactivating genes upon insertion or by providing promoters that increase the transcription of downstream genes. Insertion of ISLEs into mycoplasma genomes can be expected to mediate high-frequency genomic rearrangements. In fact, chromosomal rearrangement activity accompanied insertion of specific ISLEs into the chromosome of clinical isolates of *M. fermentans*. Insertion occurred at extremely high frequencies, as detected by genomic hybridization analysis of randomly subcloned colonies (Hu et al., 1998). More recently, *M. fermentans* was also found to carry a large (≈ 23-kb) genetic element that is present in four copies in the *M. fermentans* PG18 chromosome, accounting for approximately 8% of the genome (Calcutt et al., 2002). These novel elements, resemble conjugative, self-transmissible integrative elements (named "constins") and, surprisingly, are devoid of known integrases, transposases or recombinases, suggesting that a novel enzyme may be employed in excision and integration of these large elements. The skewed distribution and varied sites of chromosomal integration of the elements among *M. fermentans* isolates and in two other mycoplasma species, suggest that these elements play a role in promoting genomic and phenotypic variations in mycoplasmas.

Epidemiology and Control

Transmission

Acquisition of mollicutes can be established by direct contact between hosts or through secondary means, such as aerosols, fomites, food, water, insect vectors or other carriers, and by nosocomial acquisition (e.g., organ or tissue transplants; Tully, 1996). Many mycoplasmas inhabit the mucous membranes of the respiratory, urogenital, or gastrointestinal tracts of vertebrates, so that the mycoplasmas can be transmitted by direct oral-to-oral, genital-to-genital, or oral-to-genital contact. Thus, mycoplasmas found in the oropharynx may be found in some cases also in the genital tract and vice versa. Respiratory aerosols or fomites play apparently the major role in transmission of respiratory tract mycoplasmas, though neonates can be infected by *U. urealyticum* through in utero infection (Taylor-Robinson and Furr, 1998).

Food (and possibly water) obtained through feeding excursions plays a role in the acquisition of mollicutes by insects, where the organisms are present in plant sap or nectar, or where such materials are contaminated with other insect-derived excretions. In some predatory insects, the mycoplasmas are acquired directly by eating other infected hosts. Insect vectors are responsible for transmission of spiroplasma and phytoplasmas from plant to plant. These transmissions usually involve a biological cycle within the insect, involving multiplication of the mollicutes in various insect tissues (adipose tissue, salivary gland, etc.) followed by reinoculation into susceptible plants (Tully and Whitcomb, 1992).

Secondary transmission of mycoplasmas can also occur through healthy carriers or through convalescent carriers recovering from acute infections, as apparently occurs in some *M. pneumoniae* respiratory infections in humans and probably in acute and chronic respiratory mycoplasmal diseases in domestic animals. Infected carriers also play an important role in the transmission of *Spiroplasma melliferum* and *S. apis* infections from foraging bees to their hives. Mollicute transmission after plant grafting of infected tissue to healthy rootstock (Tully and Whitcomb, 1992) or through human organ or tissue transplantation have also been described (Tully, 1996). Semen contaminated with mycoplasma is an important factor in dissemination of sexually transmitted diseases in a variety of hosts and should be considered particularly in artificial insemination programs in humans and bovines (Kanakas et al., 1999).

The upper respiratory and genital tracts of human newborns are first colonized with mycoplasmas acquired during passage through the female birth canal. There is now substantial evidence that mycoplasma colonization can occur even earlier in utero by organisms introduced during fertilization or during early pregnancy. Generally, neonatal colonization with both human oral and genital mycoplasmas does not persist and the number and type of mycoplasmas decrease with age. Subsequent reacquisition of the human urogenital mycoplasma flora appears to be directly related to sexual contacts (Taylor-Robinson and Furr, 1998; Blanchard and Bebear, 2002). In vertebrates, acquisition from the maternal genital tract, and in utero transmission (including egg transmission in birds), apparently represents the initial mechanism of infection. Transovarian transmission of spiroplasmas has been well established in *Drosophila* species (Williamson and Poulson, 1989).

Host factors also play an important and complex role in determining whether an acquired mycoplasma behaves as a pathogen or is avirulent. Endogenous mycoplasmas may become pathogenic when the human host immune system has been compromised or when surgical intervention or trauma allows mycoplasma commensals to enter the circulation or other host tissues. Common commensals, such as *M. hominis*, *M. salivarium* and *U. urealyticum* have been shown to induce septicemia and overt mycoplasma invasion of various host tissues and organs, with localization in joints being especially prominent (Blanchard and Bebear, 2002).

Because *M. pneumoniae* infections are so common in humans, epidemiological data on these infections are abundant. One of the most puzzling features of *M. pneumoniae* pneumonia is the age distribution of patients. In a survey conducted between 1964 and 1975 of more than 100,000 individuals in the Seattle area, the age-specific attack rate was highest among 5- to 9-year-old children (Foy et al., 1979). Rates of *M. pneumoniae* pneumonia in the youngest age group, 0–4 years old, were about one-half those in school-age children, but considerably higher than those in adults. *Mycoplasma pneumoniae* pneumonia was rarely observed in infants younger than 6 months, suggesting maternally conferred immunity (Fig. 19). *Mycoplasma pneumoniae* accounts for 8–15% of all pneumonias in young school-age children. In older children and in young adults, the organism is responsible for approximately 15–50% of all pneumonias. Infection with *M. pneumoniae* is worldwide and endemic; it occurs all year round but shows a predilection for the colder months, apparently because of the greater opportunity for transmission by droplet infection. *Mycoplasma pneumoniae* appears to require close personal contact to spread; successful spreading usually occurs in
Fig. 19. Incidence of *M. pneumoniae* pneumonia in Seattle by age, for two epidemics (1966–67 and 1974) and the endemic period (1967–73). From Foy et al. (1979).

families, schools and institutions. The incubation period is relatively long, ranging from 2–3 weeks (Talkington et al., 2001; Jacobs, 2002).

Ureaplasma urealyticum is spread primarily through sexual contact. Colonization has been linked to the frequency of sexual intercourse and the number of sexual partners. Women may be asymptomatic reservoirs of infection (Taylor-Robinson and Furr, 1998).

Prevention

The frequent failure of antibiotics and other therapeutic approaches to eradicate mycoplasmas and abort the infectious disease process has led to the conclusion that development of effective vaccines is the most promising approach to control mycoplasma infections in humans and animals. The many efforts to develop effective and safe mycoplasmal vaccines have been only partially successful. The overall success obtained with formalin-inactivated *M. pneumoniae* vaccines in humans has been extremely disappointing, although fully inactivated vaccines and live attenuated vaccines have had some success in control of some mycoplasma diseases in animals. No acceptable live vaccine has been developed for human use (reviewed in Ellison et al. [1992]). Prior natural infection appears to provide the most effective resistance; however, evidence shows that *M. pneumoniae* infections recur at intervals of several years (Lind et al., 1997). These observations suggest that immunity to a single natural infection is relatively short-term, particularly in children, and it may be unrealistic to expect more, or even as much, from artificially induced immunity.

Attenuation of mycoplasma strains tends to reduce virulence and immunogenicity. In most cases, attenuated viable vaccines do not reach the level of protective efficiency required from a commercial vaccine. Killed *M. pneumoniae* vaccines administered intranasally to hamsters are relatively inefficient unless boosted by parenteral inoculation of vaccine (Ellison et al., 1992). Intranasal immunization may be ineffective because the antigenic mass is not retained for a sufficient period in the lungs. On the other hand, parenteral killed vaccines, particularly if combined with adjuvant, do produce adequate protection in terms of reducing pneumonia but have only a minimal effect on the number of organisms growing in the lungs. A similar protective effect can be achieved briefly by inoculation with hyperimmune serum. In summary, a single dose of vaccine in a form suitable for clinical use is unlikely to produce lasting immunity to *M. pneumoniae* infection. Stimulation of systemic antibodies may prevent the clinical manifestations of pneumonia, but additional local stimulation with live or killed organisms may be necessary to evoke resistance to colonization. The advantages of live vaccines are well established, but they frequently suffer from some deficiencies. Thus, the live *M. gallisepticum* F-strain provides good protection but may be pathogenic to young chicks. Vaccines based on temperature-sensitive mutants of *M. gallisepticum* are safer than the F-strain but do not afford the same level of protection. Consequently, Papazisi et al. (2002b) proposed a new approach, based on employing a live, attenuated *M. gallisepticum* strain R_{high} that had lost the *gapA* and *crmA* adhesin genes. Insertion of the adhesin *gapA* gene into the chromosome of the attenuated strain resulted in the expression of a high level of Gap A on the mycoplasma cell surface. Vaccination of chicks with this genetically modified strain produced a high level of antibodies to Gap A, protecting the chicks against infection with the virulent R_{low} *M. gallisepticum*.

An approach worth pursuing is the preparation of vaccines made of antigenic components specifically related to the mycoplasma-host cell interaction, such as mycoplasmal adhesins. Guinea pigs preimmunized with purified P1 adhesin protein and subsequently infected with *M. pneumoniae* showed increased levels of *M. pneumoniae*-specific IgG, IgA and adherence-inhibiting antibodies. However, these animals developed severe lung lesions on challenge, suggesting that it may well be harmful to vaccinate the host with the P1 protein, inasmuch as it may sensitize the host to the extent that subsequent infection will potentiate host response and lead to a more severe disease (Jacobs et al., 1988; Razin and Jacobs, 1992). Another mycoplasmal protein vaccine was developed more recently against *M. hyopneumoniae* (Chen et al., 2001). This vaccine was composed of a recombinant chimera of the nontoxic moiety of *Pseudomonas* exotoxin with a fragment of a *M. hyopneumo-*

niae cytadhesin overexpressed in *E. coli*. The serological response of pigs to this chimeric protein was promising, but more work is needed to show the effectivity of this vaccine under field conditions.

DNA Vaccines Genetic immunization (DNA vaccines) is a novel promising approach to vaccine production that has many of the advantages of live and attenuated vaccines but with no risk of infection. Confounding factors, such as adjuvant, hapten carriers, or denaturing agents are not needed. Vaccine production involves introducing DNA encoding a pathogen protein into host cells, using an expression library of the pathogen. The first step in the process is the successful transfection of cells that take up the plasmid. The cDNA, with a strong mammalian promoter in the construct, directs the synthesis of mRNA, leading to the synthesis of the immunogen protein. If the transfected cell is a professional antigen-presenting cell (APC, e.g., a dendritic cell) that expresses class I and II MHC proteins as well as co-stimulatory molecules, the process of antibody production can proceed (Lai and Bennett, 1998). The DNA vaccine induces effectively antibodies as well as cytotoxic T lymphocytes. Thus both humoral and cell-mediated responses are induced—a distinct advantage. Barry et al. (1995) prepared an *M. pulmonis* library by fusing digested mycoplasmal DNA onto the last exon of the gene encoding human growth hormone (hGH), using a cytomegalovirus vector, so that hGH-*M. pulmonis* antigens might be secreted. Theoretically, a library expressing the entire genome of a pathogen could be used as a vaccine. Barry et al. (1995) found that about 1 ng DNA was required to produce an immune response by genetic immunization into the skin. Mice immunized with *M. pulmonis* libraries and challenged had no culturable mycoplasmas and no lung lesions.

Lai et al. (1994) constructed an *M. pulmonis* genomic library cloned in λgt 11 transfected into *E. coli*. Clones of *E. coli* expressing a fusion protein reactive with anti-*M. pulmonis* antibodies were transferred orally or intravenously into mice. Expression of fusion proteins in the mice was induced by adding isopropyl-β-D-thiogalactopyranoside (IPTG) into the drinking water, resulting in local and systemic antibody production and effective protection of the animals against large numbers of virulent *M. pulmonis*. DNA vaccines also could be used to treat animals already infected with *M. pulmonis*. When infected mice were immunized with the DNA vaccine one week after infection, the numbers of organisms recovered from tracheolung lavage fluids gradually decreased and were totally eliminated by four months (Lai et al., 1997).

The epitope important as an immunogen may be selected by isolating the dominant antigen, preparing a monoclonal antibody to it, and using this antibody to select the *E. coli* clone producing the specific epitope-bearing fusion protein. Thus, the DNA vaccine is controllable. Such a specific DNA vaccine was developed for *M. hyopneumoniae*. Following screening of the mycoplasmal clone bank with hyperimmune pig serum, Fagan et al. (1996) identified a clone with a sequence homology to the R2 subunit of ribonucleotide reductase. This clone was expressed in *E. coli* as an 11-kDa protein fused to β-galactosidase. Assessment of the vaccine potential of the fusion protein in pig trials showed the vaccinated pigs to be significantly protected against challenge with a virulent *M. hyopneumoniae*. An attenuated *Salmonella typhimurium aroA* strain used as a vector for delivery of the above immunogenic *M. hyopneumoniae* fusion protein did protect mice against experimental infection with *M. hyopneumoniae* and is thus a potentially cheap and easily adminstrable oral vaccine for swine (Fagan et al., 1997). Efforts to develop an effective DNA vaccine against *M. hyopneumoniae* are still under way, suggesting the failure of the above-described DNA vaccines to provide satisfactory protection of swine in field trials. A recent trial is that reported by Chen et al. (2003). They constructed a plasmid vector carrying the P42 heat shock protein gene of *M. hyopneumoniae* driven by the potent cytomegalovirus promoter. Injection of the plasmid into mice induced both humoral and cellular responses. The antiserum from the immunized mice inhibited growth of *M. hyopneumoniae*. One can only hope that this vaccine will offer better protection of swine than the previous DNA vaccines.

A novel genetic strategy to control phytoplasma diseases has been based on expression in plants of antibodies (plantibodies) that are able to interfere with multiplication of the pathogen. Le Gall et al. (1998) engineered a gene of a single-chain variable fragment antibody to a major membrane protein of the stolbur phytoplasma. They cloned it in a plasmid of *Agrobacterium tumefaciens* and introduced it into tobacco plants. The transformed plant carried the transgene. When grafted on a stolbur-infected tobacco root stock, the transgenic tobacco shoots grew free of symptoms, while normal tobacco shoots showed severe stolbur symptoms.

Because the great potential of DNA vaccines is not in doubt, rapid development of this new generation of vaccines can be expected. Whether the high hopes for these vaccines are justified will have to await the results of large-scale field trials.

TREATMENT The mycoplasmas are sensitive to most broad-spectrum antibiotics (such as the tetracyclines and macrolides, as well as the newer quinolones) but are resistant to antibiotics that specifically inhibit bacterial cell wall synthesis. Susceptibility profiles of human mycoplasmas to a variety of the classical as well as the newer antibiotics can be found in Hannan (2000) and Bebear and Bebear (2002).

Tetracyclines are widely used in treatment of genital tract infections, but macrolides are also widely used for respiratory tract infections. Erythromycin, the newer macrolides, ketolides, and newer quinolones (when compared with tetracyclines) have equal or sometimes greater activity against mycoplasmas. Most of the effective antibiotics only inhibit mycoplasma multiplication but do not kill them. The ketolides and some quinolones also have some mycoplasmacidal activity (Taylor-Robinson and Bebear, 1997; Waites et al., 2003).

Mycoplasmas may develop resistance, either by gene mutation, by acquisition of a resistance gene, or by active efflux of the antimycoplasmal agent (Bebear and Bebear, 2002; Pereyre et al., 2002; Raherison et al., 2002; Reinhardt et al., 2002). Thus, integration of the *tetM* gene into the *U. urealyticum* or the *M. hominis* chromosome renders these mycoplasmas resistant to tetracycline. The resistance factor could be transferred from other tetracycline-resistant bacteria by a process resembling conjugation (Roberts and Kenny, 1987).

Mycoplasmas may be difficult to eradicate from human or animal hosts or from contaminated cell cultures by antibiotic treatment, because specific mycoplasma are either resistant to the antibiotic, lack mycoplasmacidal activity, or are in an intracellular location (see the section Intracellular Location). As expected, mycoplasma eradication is particularly difficult in immunosuppressed or immunodeficient patients.

Pathogenicity

Most mollicutes live as commensals, and in many arthropods they may even be considered as symbionts. In the case of pathogenic mycoplasmas, infections are rarely of the fulminant type but rather follow a chronic course. Mycoplasmas are arguably close to "ideal parasites," usually living in harmony with their host. Extensive descriptions of the diseases caused by mollicutes in humans, animals, plants and insects can be found in *The Mycoplasmas*, volumes IV (Razin and Barile, 1985) and V (Whitcomb and Tully, 1989), in Maniloff et al. (1992) and in Razin and Herrmann (2002). A variety of diseases of unknown etiology were also linked to mycoplas-

mas (Baseman and Tully, 1997). These include the possible role of mycoplasmas as cofactors to AIDS pathogenesis, Gulf War syndrome, and other diseases of unexplained etiology, such as chronic fatigue syndrome, Crohn's disease, and various arthritides (Lo et al., 2000; Endresen, 2003). Although the association of mycoplasmas with many of these diseases remains doubtful, the possible role of mycoplasmas in AIDS activation has attracted the most attention during the last decade. The substantial number of studies carried out on the AIDS-associated mycoplasmas, *M. fermentans* and *M. penetrans*, have advanced considerably our knowledge of mycoplasma cell biology and host immune modulation by mycoplasmas, as evidenced in many sections of this chapter. However, thus far the proposed role of mycoplasmas in AIDS activation remains controversial and doubtful (Brenner et al., 1996; Baseman and Tully, 1997; Taylor-Robinson and Furr, 1998).

Mycoplasmas were suspected long ago as causative agents of rheumatoid arthritis (RA), but solid evidence to support this was lacking. The recent emphasis on the immunomodulatory effects by mycoplasmas (see the section Immune System Modulation) and more so, detection of mycoplasmal DNA, particularly that of *M. fermentans*, in synovia of RA patients (Schaeverbeke et al., 1999) as well as the prevalence of antibodies to *M. fermentans* in the patients (Horowitz et al., 2001) suggest that in some RA patients *M. fermentans* may play a role in initiating or perpetuating synovitis (Blanchard and Bebear, 2002).

Disease Manifestations

The effects of *M. pneumoniae* on humans include subclinical infection, upper respiratory disease, and bronchopneumonia. Most human infections do not progress to a clinically evident pneumonia. When pneumonia occurs, the onset generally is gradual and the clinical picture is one of mild to moderately severe illness, with early complaints referable to the lower respiratory passages. Radiography frequently reveals evidence of pneumonia before physical signs are apparent. Involvement is usually limited to one of the lower lobes of the lungs, and the pneumonia is interstitial or bronchopneumonic. The course of disease varies; remittent fever, cough and headache persist for several weeks. One of the most consistent clinical features is a long convalescence, which may extend 4–6 weeks. Few fatal cases have been reported. Several complications following *M. pneumoniae* infections have been noted, including hemolytic anemia, polyradiculitis, encephalitis, aseptic meningitis, and central nervous system illness such as the Guillain-Barré

syndrome. In addition, pericarditis and pancreatitis have been observed. Although these sequelae have been commonly related to the suspected immunopathology of *M. pneumoniae* disease, *M. pneumoniae* has been increasingly demonstrated in the affected organs by PCR, or in some cases even by culture (Narita et al., 1995; Bencina et al., 2000).

Growing evidence suggests that *Ureaplasma urealyticum* causes nongonococcal urethritis in men that are free of *Chlamydia trachomatis*, an established agent of nongonococcal urethritis. The wide occurrence of *U. urealyticum* in sexually active, symptom-free adults hampers research in this field. Evidence is based primarily on the production of nongonococcal urethritis symptoms in ureaplasma-free and chlamydia-free volunteers by intraurethral inoculation of *U. urealyticum*. Ureaplasmas have also been associated with chorioamnionitis, habitual spontaneous abortion, and low-weight infants (Gerber et al., 2003). *Mycoplasma hominis*, a common inhabitant of the vagina of healthy women, becomes pathogenic once it invades the internal genital organs, where it may cause pelvic inflammatory diseases such as tubo-ovarian abscess or salpingitis (Taylor-Robinson and Furr, 1998).

Mycoplasma genitalium, isolated in 1981 from the urethral discharge of two homosexual men, may account for the tetracycline-responsive, nongonococcal urethritis cases in which chlamydias and ureaplasmas could not be isolated (about 20% of all cases). However, *M. genitalium* is so fastidious that very few clinical isolates have so far been made on the best mycoplasma media available. Only the recent application of specific PCR amplification of the organism's DNA in clinical specimens has provided experimental proof for the relative prevalence of *M. genitalium* in the human urogenital tract and its apparent role in chronic male urethritis (Taylor-Robinson and Furr, 1998; Totten et al., 2001) and possibly also in acute endometritis and cervicitis in women (Cohen et al., 2002; Manhart et al., 2003).

Many *Mycoplasma* species are established pathogens of farm animals, causing contagious pleuropneumonia, mastitis, and conjunctivitis in cattle, goats and sheep, and chronic respiratory disease and arthritis in swine, chicken and laboratory animals (Frey, 2002).

Molecular Basis of Mycoplasma Pathogenicity

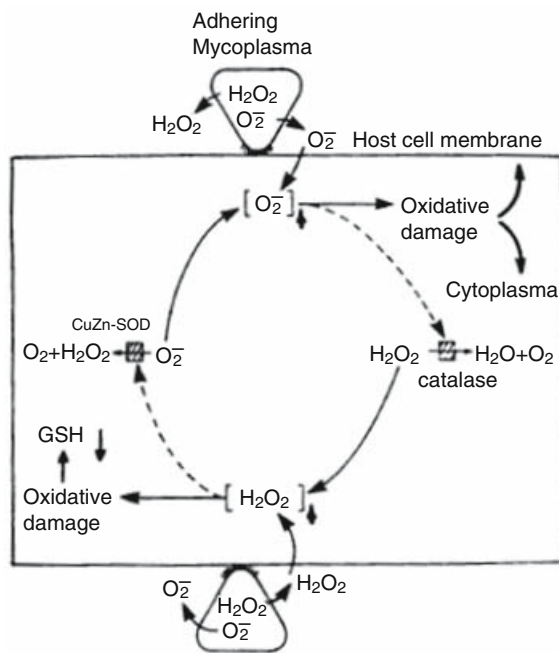
OXIDATIVE DAMAGE AND MEMBRANE FUSION Potent toxins have not been associated with mycoplasmas. The mildly toxic byproducts of mycoplasma metabolism (such as hydrogen per-


Fig. 20. Schematic presentation of the proposed mechanism for oxidative tissue damage by mycoplasmas. GSH, glutathione and SOD, superoxide dismutase. From Kahane (1984).

oxide and superoxide radicals) have been accused of causing oxidative damage to host cell membranes. Extensive studies by Almagor et al. (1986) led to the formulation of the following pathological events of *M. pneumoniae* infection (Fig. 20). The H_2O_2 and superoxide radicals (O_2^-) continuously generated by the adhering mycoplasmas penetrate into the host cell. As a result of O_2^- accumulation, gradual irreversible inhibition of host cell catalase is induced, thereby causing intracellular H_2O_2 accumulation. The latter, in turn, may cause product inhibition of the host cell superoxide dismutase. The process is self-perpetuating and results in increased levels of O_2^- and H_2O_2, which induce progressive oxidative damage to vital cell constituents. Thus, malonyldialdehyde, a known oxidative product of membrane lipids, was shown to accumulate in cells infected by *M. pneumoniae*. Supportive of the role of hydrogen peroxide in mycoplasma pathogenicity are the recent findings of Vilei and Frey (2001) showing that the higher virulence of the African strains of *M. mycoides* subsp. *mycoides* SC may be associated with their ability to transport and metabolize glycerol. Peroxide production in glycerol-containing growth media was high for the African strains but very low for the much less virulent European strains that lack the genes for glycerol transport. A question most frequently asked is how the mycoplasmas, lacking antioxidants like catalase and superoxide

dismutase, protect themselves against oxidative stress. The finding by Dhandayuthapani et al. (2001) of methionine sulfoxide reductase in *M. pneumoniae* and *M. genitalium*, an antioxidant enzyme that catalyzes the reduction of methionine sulfoxide residues in proteins to methionine, may play an important role in protecting mycoplasma protein structure from oxidative damage.

The lack of a cell wall in mycoplasmas is expected to facilitate direct contact of the mycoplasma membrane with that of its eukaryotic host, creating a condition which, in principle, could lead to fusion of the two membranes, enabling transfer or exchange of membrane components and injection of mycoplasmal cell constituents into the host cell (Razin et al., 1998; Rottem, 2002c). Unique *M. fermentans* glyceroglycolipids containing phosphocholine (Rottem, 2002a) exhibit fusogenic properties, in addition to serving as important surface immunogens inducing cytokine secretion. The possibility that the synthesis of the choline-containing lipids by *M. fermentans* may cause choline depletion in the host has been suggested by Ben-Menachem et al. (2001). Choline is an essential component of eukaryotic cell membranes. *Mycoplasma fermentans* was found to deplete the choline component of an astrocyte cell culture leading to apoptosis of the cells, an effect that could be prevented by the addition of free choline to the growth medium. Whether choline deficiency can occur in patients infected by *M. fermentans* is obviously a moot point.

INTRACELLULAR LOCATION The uptake of human and animal mycoplasmas by polymorphonuclear leukocytes and macrophages was shown (Marshall et al., 1995), and intracellular location of spiroplasmas and phytoplasma within salivary gland cells of insects is an integral part of their life cycle. However, the question of whether animal mycoplasmas can enter epithelial cells has not been easy to resolve, and for a long time, this question was answered in the negative. The stimulus to re-examine this issue came from the studies by Lo (1992) showing the intracellular location of *M. fermentans* (strain incognitus) in a variety of nonphagocytic cells in AIDS patients. This finding was strengthened by the discovery of a new human mycoplasma capable of entering a variety of human cells in vivo and in vitro, named accordingly *M. penetrans* (Lo et al., 1993; Fig. 21).
Fig. 21. Adhesion and invasion of mammalian cells by *Mycoplasma penetrans*. Many organisms line along the cell surface with their tip-like structure of densely packed fine granules compartment (F) inserted into the eukaryotic cell. The body compartment of loosely packed coarse granules (C) remains outside. Inset shows the active invasion process at higher power. Bars represent 100nm. From Lo et al. (1993).

The mechanism of cell entry by mycoplasmas is still unclear. Even though mycoplasmas, such as *M. penetrans* and *M. genitalium* appear to enter the cells through their specialized tip structure (Lo et al., 1993; Jensen et al., 1994), other mycoplasmas shown to internalize (e.g., *M. fermentans* and *M. hominis*) have no tip structures (Taylor-Robinson et al., 1991). Following contact of *M. genitalium* with human lung fibroblasts, the plasma membrane of the cells appeared to be forced inward to form a cup or a depression. The membrane pockets resembled clatherin-coated pits, suggesting that the mycoplasma might adhere to and enter the cells by a site-directed, receptor-mediated event, resembling cell entry by chlamydia (Mernaugh et al., 1993). Host cell entry appears to depend on the assembly of actin microfilaments and organized microtubules, as cytochalasin D prevented invasion by *M. penetrans* (Rottem, 2002c). Apparently, *M. penetrans* stimulates host cell phospholipases to cleave membrane phospholipids, thereby initiating a signal transmission cascade. This cascade triggers cytoskeletal rearrangements, allowing the internalization of *M. penetrans*. The presence in the host cell cytoplasm of mycoplasmas, some of which may not even be enclosed within a vacuole, may expose the cytoplasm and the nucleus to mycoplasmal hydrolytic enzymes, such as proteases, nucleases and phospholipases (Rottem, 2002c).

Whether the mycoplasmas replicate intracellularly remains to be resolved. The study by Dallo and Baseman (2000) indicated that intracellular *M. pneumoniae* and *M. penetrans* infectivity in human cells could be detected for over 6 months, while *M. genitalium* survival in the cells was detected by PCR for long periods. Moreover, specific inhibition of eukaryotic nuclear DNA synthesis by aphidicolin enabled the selective detection of mycoplasmal DNA synthesis, supporting their intracellular replication (Dallo and Baseman, 2000).

Notably, intracellular location, if even for a short period, may protect the mycoplasmas against the effects of the host immune system and antibiotics and, to some extent, account for the difficulty of eradicating mycoplasmas from infected cell cultures. Thus, intracellular residence, which sequesters mycoplasmas, promotes the establishment of latent or chronic infection states, and circumvents mycoplasmacidal immune mechanisms and selective drug therapies (Bebear and Bebear, 2002). Different aspects of the interaction of mycoplasmas with host cells, including fusion of the parasite with the host cell membrane, invasion into host cells, and the implications of these processes on mycoplasma pathogenicity, have been recently reviewed in depth by Rottem (2003).

CLASTOGENIC AND ONCOGENIC EFFECTS The potent mycoplasmal nucleases, combined with superoxide radicals, may be responsible for clastogenic effects. In fact, reports on chromosomal aberrations, altered morphology, and cell transformation in cell cultures infected by mycoplasmas have appeared rather sporadically since the early 1960s. Interest in this subject has been rekindled following the claims that *M. penetrans* may be a cofactor in the induction of HIV-associated Kaposi's sarcoma. Results of experiments with cultured mouse embryo cells reported by Tsai et al. (1995) and by Feng et al. (1999b) appear to support an oncogenic potential of the AIDS-associated mycoplasmas *M. fermentans* and *M. penetrans*. However, instead of acute transformation, a multistage process in promotion and progression of malignant cell transformation with long latency was noted. Only after 18 passages (one week per passage) of persistent infection with mycoplasmas, an irreversible form of transformation, that included the ability to form tumors in mice, was achieved. Of note, however, is that the tumors had developed very slowly and not in all mice. The irreversible phase of transformation coincided with permanent karyotypic alterations. Once induced, chromosomal alterations continued to accumulate both in cultured cells and in animals without the continued presence of the transforming mycoplasmas. Hence, the mycoplasma-mediated multistage oncogenesis exhibited many characteristics found in the development of human cancer (Lo, 2002). Nevertheless, the real biological significance of these findings warrants further investigation.

Another related issue concerns the induction of apoptosis by mycoplasma infection (reviewed by Lo [2002]). Endogenous nucleases are generally considered to catalyze DNA fragmentation, a common biochemical hallmark of apoptosis. In light of the relatively large amounts of nucleases expressed by mycoplasmas (Bendjennat et al., 1999), Paddenberg et al. (1998) tested the effects of *M. hyorhinis* infection of NIH 3T3 cells, checking for parameters characteristic of apoptosis. The infected cells exhibited intranucleosomal DNA degradation into multimers of 200 bp, forming a ladder in agarose gels. Nuclease activities were detected in cell homogenates and culture supernatants. Their mycoplasmal origin was indicated by inhibition of their expression following chloramphenicol treatment of the infected cells. Furthermore, enriched mycoplasmal nucleases, purified from culture supernatants of *M. hyorhinis* and *M. penetrans* could reproduce the apoptotic effects of mycoplasmal infection (Paddenberg et al., 1998; Bendjennat et al., 1999). Apoptotic effects were also observed in lymphocyte and epithelial tumor cell lines

infected by mycoplasmas, pointing to the possibility that the numerous cases of "spontaneous apoptosis" reported in cell cultures are, in fact, the results of an undetected mycoplasma infection (Paddenberg et al., 1998; Stolzenberg et al., 2000). The finding that *U. urealyticum* induces apoptosis in human lung epithelial cells and macrophages may support the proposed role of the ureaplasmas in chronic lung disease of premature infants (Li et al., 2002). Some insight into the mycoplasmal cell components that induce apoptosis has been presented by Into et al. (2002) showing that mycoplasmal membrane lipoproteins induce necrotic and apoptotic cell death in monocytes-macrophages and lymphocytes. Apoptosis was induced by caspases (cysteine proteases) through TLR2 (Toll-like receptor 2)-mediated signaling.

PATHOGENCITY ASSOCIATED GENES A promising genetic approach, based on transposon Tn*4001* mutagenesis, has been applied to study pathogenicity factors of *S. citri* (Foissac et al., 1997b; Gaurivaud et al., 2000a, b). One of the Tn*4001* mutants did not multiply in the leafhopper vector and therefore could not be transmitted to the plant. Another mutant multiplied well in the plant but did not induce symptoms. In this non-pathogenic mutant, Tn*4001* was found inserted in the spiroplasmal PTS fructose operon, abolishing the ability of the organism to utilize fructose, probably affecting in this way its pathogenicity. The most likely explanation is that utilization of fructose in the plant sieve tubes by the pathogenic spiroplasmas may interfere with the normal physiology of the plant causing chlorosis, stunting and wilting (Bai and Hogenhout, 2002). Of interest would be whether pathogenicity of the mutant can be restored by complementation with the wildtype genes, like the successful restoration of motility in a Tn*4001* *S. citri* mutant by complementation with the wildtype genes (Jacob et al., 1997; see the section Motility and Cytoskeletal Elements). In continuation of this line of research, Jagoueis-Eveillard et al. (2001) embarked on the study of plant genes that are deregulated following infection by mollicutes. These rather preliminary studies revealed that cDNAs of periwinkle plants are differently expressed following infection with *S. citri* or by phytoplasmas. Clearly, much more work has to be carried out to identify the metabolic pathways modified during plant-mollicute interactions, but the genetic approach appears to be very promising.

The lysogenic bacteriophage MAV1 infecting *M. arthritidis* (Voelker and Dybvig, 1999; Washburn and Cole, 2002) appears to play an important role in the pathogenicity of this murine mycoplasma. All virulent *M. arthritidis* strains carry MAV1 DNA integrated at various sites of the mycoplasmal chromosome, whereas avirulent strains lack MAV1. Furthermore, the arthritogenic potential of a low-virulence *M. arthritidis* strain could be considerably enhanced by lysogenization with MAV1 (Voelker et al., 1995). The mechanism by which MAV1 enhances virulence is not known. The fact that several MAV1-negative strains are not completely avirulent suggests that MAV1 integration may activate other virulence factors, such as the *M. arthritidis* superantigen, (known as MAM; see the section Immune System Modulation), or increase the expression of *M. arthritidis* cytadhesins. The recent identification of an MAV1 gene that apparently encodes a lipoprotein may provide some direction to future research, by assuming that the phage-derived lipoprotein is incorporated into the cell membrane of the avirulent *M. arthritidis* and induces in some unknown way the conversion of the avirulent to the virulent phenotype (Voelker and Dybvig, 1999; Tu et al., 2002).

Adhesion to Host Cells

Most human and animal mycoplasmas adhere tenaciously to the epithelial linings of the respiratory or urogenital tract, rarely invading tissues. Hence, they may be considered as surface parasites. Adhesion of mollicutes to host cells is a prerequisite for colonization by the parasite and for infection. The loss of adhesion capacity by mutation results in loss of infectivity, and reversion to the cytadhering phenotype is accompanied by regaining infectivity and virulence. The best-defined mycoplasmal adhesins (membrane components responsible for adhesion) are those of *M. pneumoniae* and *M. genitalium*. Detailed information on the genes and molecular properties of the encoded adhesin proteins of these mycoplasmas (P1, MgPa and P30) can be found in several reviews and articles (Razin and Jacobs, 1992; Razin et al., 1998; Krause and Balish, 2001; Balish and Krause, 2002; Musatovova et al., 2003).

Although the above-mentioned adhesins fulfill the major role in cytadhesion of *M. pneumoniae* and *M. genitalium*, the process appears to be multifactorial, involving in addition to the major adhesins, a number of accessory membrane proteins. These accessory proteins act in concert with cytoskeletal elements to facilitate the lateral movement and concentration of the adhesin molecules at the attachment tip organelle and provide the scaffolding for the assembly of this organelle (see the section Motility and Cytoskeletal Elements). Much of the recent effort, forming part of the *M. pneumoniae* genome project, has been directed to the molecular definition of

the attachment organelle components, forming part of the mycoplasmal cytoskeleton ("Triton shell"). Some of the genes and the encoded proteins of the *M. pneumoniae* Triton shell (30-kDa, 40-kDa, 90-kDA, P65, P200, HMW1, HMW2 and HMW3) have been identified and characterized. Interestingly, they are proline rich and exhibit repeat sequences and other motifs characteristic of eukaryotic cytoskeletal proteins. Thus, the C-terminal domain of P30 shows substantial sequence homology with the C-terminus of P1 and exhibits immunological crossreactivity with fibrinogen, keratin and myosin—a finding which may be associated with the autoimmune sequelae following *M. pneumoniae* infections (Romero-Arroyo et al., 1999).

The HMW1 protein seems to be responsible for targeting (trafficking) the P1 adhesin to the attachment organelle (Balish et al., 2001), whereas the 40- and 90-kDa proteins anchor P1 to the membrane of the organelle in a way that allows mutual and intimate interactions of P1 with cytoskeletal-forming or -associated proteins. Loss of the 40- and 90-kDa proteins by mutation results in the loss of the attachment organelle, cells becoming spherical and nonadherent (Layh-Schmitt and Harkenthal, 1999). The genes for HMW1 and HMW3 are part of the *hmv1* locus, along with the gene for P30. The *hmv2* gene for HMW2 lies about 160kb from the *hmw1* locus. Yet, transposon insertions into *hmw2* resulted in the simultaneous loss of HMW1, HMW3 and P65 as well as of several other cytadherence-associated proteins, probably due to accelerated endogenous proteolysis (Jordan et al., 2001; Krause and Balish, 2001). Thus, HMW2 apparently functions as a cytoskeletal organizer and is required for the stable maintenance of the above proteins (Balish et al., 2003). The complex interrelationship between the components of the attachment organelle underscores the need for the proper ordered assembly of this organelle that must be coordinated also with cell division (Krause and Balish, 2001; Seto et al., 2001).

The avian pathogen *M. gallisepticum* carries also an attachment organelle (Fig. 6) and its cytadherence, like that of *M. pneumoniae*, is a complex multifactorial process involving the coordinate action of a primary cytadhesin molecule GapA and several additional cytadherence-associated proteins in a manner reminiscent of the complex cytadherence mechanism of *M. pneumoniae*. The gene *crmA* (cytadherence-related molecule A), located immediately upstream of *gapA,* has significant sequence homology to the ORF6 of the *M. pneumoniae* P1 operon (Papazisi et al., 2000; Mudahi-Orenstein et al., 2003; Winner et al., 2003) and must be present together with GapA to mediate cyt-

adherence of *M. gallisepticum* (Papazisi et al., 2002a). An *M. gallisepticum* gene encoding a 105-kDa protein, showed 45% homology to the *M. pneumoniae* P1 gene, 46% homology to the *M. genitalium* MgPa adhesin gene, and 47% homology to the *M. pirum* P1-like protein gene (Goh et al., 1998). Along the same line, the P30 adhesin gene of *M. pneumoniae* shows 40.9% identity with the 32-kDa protein gene of *M. gallisepticum*, and 31.4% identity with the *M. genitalium* P32 cytadhesin gene (Hnatow et al., 1998). Collectively, these findings suggest the presence of a family of cytadhesin genes conserved among the pathogenic mycoplasmas belonging to the pneumonia phylogenetic clade. One may speculate that these cytadhesin genes originate from the same ancestral operon.

Mycoplasma hyopneumoniae adheres to the cilia of the respiratory epithelium of swine (Young et al., 2000). The gene coding for the ciliary adhesin was cloned and sequenced, and its 94–97-kDa protein product was characterized (Minion et al., 2000). The R1 region near the carboxy terminus of the protein mediates the adhesion of the mycoplasmas to the cilia. Eight R1 repeating units are required for cilia binding. Interestingly, *M. flocculare*, genetically closely related to *M. hyopneumoniae*, lacks the 97-kDa ciliary cytadhesin gene (Blank and Stemke, 2001), possibly explaining the lack of pathogenicity of this mycoplasma to swine. Cytadherence of *M. hyopneumoniae* causes a fast increase in the intracellular free Ca^{+2} concentration in the infected porcine ciliated tracheal epithelial cells, probably causing damage and loss of the ciliary epithelium (Park et al., 2002).

The receptors identified so far on the host cell membranes responsible for mycoplasma attachment are mostly sialoglycoconjugates and sulfated glycolipids (Razin and Jacob, 1992; Zhang et al., 1994; Kitzerow et al., 1999). The glycoprotein fibronectin, known to serve as an host receptor in the binding of streptococci, staphylococci, mycobacteria, borrelia and treponema appears also to serve as a receptor in the binding of *M. penetrans* (Giron et al., 1996) and of *M. pneumoniae* (Dallo et al., 2002). Somewhat unexpected was the identification of the cytoplasmic elongation factor Tu and the E1β subunit of pyruvate dehydrogenase as the mycoplasmal fibronectin binding proteins. Apparently, the *M. pneumoniae* EF-Tu and the pyruvate dehydrogenase subunit, in addition to their major cytoplasmic biosynthetic and metabolic roles, can be translocated to the cell surface and show multifunctionality. Along this line is the recent identification of glyceraldehyde-3-phosphate dehydrogenase of *M. genitalium* acting, in addition to its important metabolic role, as an adhesin to host cell surface mucin (Alvarez et al., 2003). It is worth mention-
Fig. 22. Selective hemadsorption of human erythrocytes to a distinct sector of a *Mycoplasma gallisepticum* colony. The phase-variable hemagglutinin is not expressed in the colony sector incapable of hemadsorption. From Athamna et al. (1997).

ing that Layh-Schmitt et al. (2000) detected the E1α subunit of pyruvate dehydrogenase as part of a cross-linked complex of the *M. pneumoniae* cytadhesins. What weight is to be given to the fibronectin cytadhesion system when compared to the well-established specific cytadhesin system (P1, P30, etc.) described above? Does the novel system fulfill an auxilliary role in mycoplasmal attachment to host cells? Obviously, these are issues that require further studies.

Not surprisingly, the surface-exposed adhesin proteins are among the most immunodominant mycoplasmal antigens. Furthermore, at least some mycoplasmal adhesins, for example, the Vaa proteins of *M. hominis* (Kitzerow et al., 1999), the Vsp proteins of *M. bovis* (Sachse et al., 2000), the MMA2 protein of *M. arthritidis* (Washburn et al., 1998), the pMSA and pMSB hemagglutinins of *M. synoviae* (Bencina et al., 2001), as well as certain hemagglutinins of *M. gallisepticum* (Boguslavsky et al., 2000; Fig. 22) exhibit the phase- and size-variation properties to be discussed in the next section.

Antigenic Variation

The mycoplasma plasma membrane, being exposed to the external environment, is the cell organelle that comes into contact with the constituents of the host immune system. Lacking the protection of a rigid cell wall, mycoplasmas are particularly sensitive to growth inhibition and lysis by antibodies and complement. Yet, despite

this marked sensitivity, mycoplasma infections are usually chronic in nature, indicating the frequent failure of the host defense mechanisms to eradicate the parasites. Apparently, many pathogenic mycoplasmas possess rather sophisticated mechanisms for rapid adaptation to changing microenvironments. Reversible switching of the expression and modification of major membrane protein antigens on the mycoplasma surface provides an effective escape from rapid destruction by the host immune system (Yogev et al., 2002). Considering the chronic nature of mycoplasmal infections, the constant selection of subpopulations, rather than adaptation of an entire population to an environmental change, is apparently responsible for the heterogenous populations of these organisms.

Table 6 presents the mycoplasmal antigenic variation systems studied thus far. The data enable some generalizations to be made: 1) Most of the systems consist of lipoproteins exposed on the external cell surface and anchored to the membrane via acyl chains. 2) The lipoproteins, functioning as dominant cell antigens, carry repetitive sequences that can spontaneously vary in size through changes in the number of these motifs (size variation). Moreover, the lipoproteins vary not only in size but also may be subjected to "on" and "off" expression states (phase variation). 3) Cloning and sequencing of the lipoprotein genes has revealed that the encoded proteins consist of three regions: the N-terminal leader region, an intermediate domain, and the C-terminal domain composed of reiterated sequences arranged in tandem. Deletion of the leader sequence on processing of the protein leaves a cysteine residue at the N-terminus free for acylation, preferentially by palmitic and myristic acids. The resulting lipid-modified protein is anchored to the outer surface of the membrane through its lipid moiety. 4) In most cases, each mycoplasma strain carries a family of lipoproteins, encoded by multiple variant genes in several versions. The genes are expressed in various combinations and at varying lengths on the organism's surface. Interestingly, in the case of a large family of genes, only one or two genes are expressed at a given time; the others are translationally silent (Bhugra et al., 1995; Glew et al., 1998; Lysnyansky et al., 1999; Sasaki et al., 2002). And 5) in many cases, the surface-exposed lipoproteins function also as adhesins.

The microbial population as a whole may spontaneously and randomly generate distinct cell populations with varied antigenic phenotypes ("heterotypes") that will survive the specific host response capable of eliminating the predominant "homotypes." The frequency of occurrence of such genetic variants is strikingly high (10^{-4} to 10^{-2} per cell per generation,

Table 6. Surface variable antigenic systems in mycoplasmas.

compared with 10^{-6} to 10^{-8} of an average mutation).

Lipoproteins may not be the only variable mycoplasma membrane proteins exposed on the cell surface. Thus, the *M. gallisepticum* PvpA is a non-lipid-modified, integral phase-variable membrane protein (Boguslavsky et al., 2000; Yogev et al., 2002). Nevertheless, this mycoplasma carries a highly immunogenic lipoprotein, pMGA, undergoing high-frequency phase variation spontaneously and independently (Glew et al., 1998). There is solid experimental evidence for the occurrence of antigenic variation in vivo. Thus, multiple isolates of *M. hominis* obtained from the same joint of a septic arthritis patient during a six-year period exhibited antigenic variation, although the strains were indistinguishable by restriction endonuclease analysis (Olson et al., 1991). Field infections of sheep and goats by *M. agalactiae* (Flitman-Tene et al., 2000) and chicken by *M. gallisepticum* (Glew et al., 2000) indicate that high-frequency antigenic phase variation occurs in vivo.

The different genetic mechanisms that form the genetic basis for antigenic variation, including strand slippage, homologous recombination, gene conversions, gene duplications, addition or deletion of tandem repetitive units, and DNA inversions (Table 6) are discussed in detail by Razin et al. (1998) and Yogev et al. (2002) and are represented schematically in Fig. 23.

VARIATIONS IN THE *M. PNEUMONIAE* P1 AND P30 ADHESIN GENES A hot spot for frequent mutation within a structural gene was found in the major P1 cytadhesin gene of *M. pneumoniae*. Reversible and spontaneous cytadherence-negative and cytadherence-positive mutants were associated with an insertion or deletion of a single nucleotide in a stretch of seven adenines. This mutation resulted in a frameshift and generation of a termination codon causing the premature termination of P1 translation (Su et al., 1989).

Large portions of the coding regions of the *M. pneumoniae* P1 operon exist as multiple extragenic copies over the chromosome, named "RepMP2/3," "Rep MP4" (originating in the P1 gene), and "Rep MP5" (originating in the ORF6 gene of the P1 operon). Relics of these sequences detected in *M. genitalium*, named "MgPa repeats," revealed strong sequence similarities to the repetitive DNA sequences from *M. pneumoniae* (Himmelreich et al., 1997). Clinical isolates of *M. pneumoniae* were found to exhibit some nucleotide sequence variation in the P1
Fig. 23. Schematic representation of regulatory and structural features of antigenic variation systems in mycoplasmas. Representative genes of distinct antigenic variation systems of six mycoplasma species are shown (not to scale) as rectangles consisting of internal blocks aligned from the 5′ end to the 3′ end of each gene. The system designation and the corresponding mycoplasma species are indicated on the left and on the right, respectively. The solid black block, labeled "Signal," contains the species-specific amino acid sequence of a putative lipoprotein signal peptide. Different hatched blocks represent system-specific in-frame reiterated sequences. The location of a homopolymeric tract of contiguous adenines (Poly-A) or of oligo-nucleotide repeats (GAA)n within the promoter region (*vlp*, *pMGA*; Yogev et al., 1991b; Glew et al., 1998) or within the coding gene region (*vaa*, *P78*; Theiss and Wise, 1997; Zhang and Wise, 1997) is shown by an arrow. Two *vsp* genes from two *M. bovis* clonal isolates, exhibiting ON or OFF expression states of the variable surface lipoprotein VspA, are shown. Site-specific DNA inversion during VspA phase variation led to an exchange of the active promoter (VspA-ON) with a non-promoter region (VspA-OFF). The two vspA-upstream regions are differently hatched. Two *vsa* genes isolated from two *M. pulmonis* variants displaying the VsaHA⁻ or the VsaHA⁺ phenotypes are shown (Simmons et al., 1996). A chromosomal fragment that inverted (indicated by "DNA Inversion") during phase transition (VsaHA⁻ ↔ VsaHA⁺) also is indicated by brackets. The direction of expression of the *vsa* gene from each variant is marked by an arrow. From Razin et al. (1998).

gene (Dorigo-Zetsma et al., 2000, 2001). The variable regions in the gene were found to correspond to regions of some of the repetitive elements, suggesting that the P1 gene may vary because of recombination between repetitive regions (Su et al., 1993; Kenri et al., 1999). Accordingly, the *M. pneumoniae* strains were divided into two groups, I and II (Su et al., 1993).

The 30-kDa (P30) adhesin protein of *M. pneumoniae* appears also to undergo size variation, losing proline-rich repetitive sequences in its C-terminal region. The truncated adhesin showed reduced antigenicity and adhesion capacity. The mechanism underlying the loss of the repeated sequences is not clear, but slipped base-pairing during replication or homologous recombination processes between repeated sequences might be

the cause of size polymorphism (Layh-Schmitt et al., 1997).

Immune System Modulation

The complex network of interactions between mycoplasmas and their host immune system involves mycoplasma-induced specific and non-specific immune reactions. Specific protective defense mechanisms include the production of systemic as well as local anti-mycoplasmal antibodies of different classes and subclasses, stimulation of cell-mediated immunity, and opsonization and phagocytosis of organisms. In some cases, for macrophages to kill invading mycoplasmas, some accessory factors provided by the host are required. Thus, alveolar macrophages (serving as the primary effector cells in early *M. pulmonis* killing in infected mice) depend on the presence in the lungs of the collectin (collagen-like lectin) surfactant protein A. Nitric oxide and superoxide radicals produced by the macrophage contribute to the killing either directly or via the production of peroxynitrite (ONOO⁻; Hickman-Davis et al., 1999).

The specific reactions elicited by invading mycoplasmas, essential for resistance and protection against mycoplasma infections, also have been shown to play a role in the development of lesions and exacerbation of mycoplasma-induced diseases (Razin et al., 1998). Humoral immunity has a major role in defense against systemic dissemination of mycoplasmal infection, but cellular immune responses may be important in exacerbation of mycoplasmal lung disease. Lack of adaptive response in severe combined immunodeficient (SCID) mice infected with *M. pulmonis* was associated with reduced lung lesion severity and with increased mycoplasmal colonization and disease at extrapulmonary sites. The transfer of naïve spleen cells from immunocompetent mice to *M. pulmonis*-infected SCID mice restored the severity of lung lesions, whereas the transfer of convalescent anti-*M. pulmonis* serum to the infected SCID mice did not restore lung lesion severity but prevented arthritis (Cartner et al., 1998).

Although mycoplasmas circumvent phagocytosis (Marshall et al., 1995; Minion, 2002), they appear to interact with mononuclear and polymorphonuclear phagocytes, suppressing or stimulating them by a combination of direct and indirect cytokine-mediated effects. For extensive recent reviews on cytokine induction by mycoplasmas, the reader is referred to Razin et al. (1998) and to Rawadi and Roman-Roman (1998). These immunomodulatory influences depend on both the immune cells and on the mycoplasma species involved. Thus, *M. dispar* manages to bypass phagocytosis by bovine alveolar macrophages because it is covered by a polysaccharide capsule which inhibits activation of macrophages and suppresses the production of tumor necrosis factor (TNF)-α and interleukin (IL-1; Almeida et al., 1992). Other mycoplasmas activate monocytes, macrophages and brain astrocytes and induce secretion of the proinflammatory cytokines TNF-α, IL-1 and IL-6, chemokines (such as IL-8, monocyte chemoattractant protein 1, macrophage inflammatory protein 1αØβ, and granulocyte-monocyte colony-stimulating factors [GM-CSFs] and prostaglandins), and active oxygen and nitrogen metabolites (Razin et al., 1998; Ribero-Dias et al., 1999; Yirmiya et al., 1999).

In addition to eliciting antimycoplasmal immune responses, mycoplasmas exert a wide range of nonspecific immunomodulatory effects upon cells comprising the immune apparatus (Reyes et al., 1999). Mycoplasmas have been shown to affect the immune system by inducing either suppression, or polyclonal stimulation of B and T lymphocytes, induction of cytokines, increasing cytotoxicity of macrophages, natural killer cells and T cells, enhancing expression of cell receptors and activation of the complement cascade. The ability of mycoplasmas to immunomodulate host immune responsiveness contributes to their pathogenic properties, enabling them to evade or suppress their host defense mechanisms and establish a chronic, persistent infection (reviewed in Razin et al. [1998]). The cytokine network plays a critical role in the maintenance of immune system homeostasis. The overproduction of some cytokines in response to mycoplasma infections may upset the fragile equilibrium and thereby contribute to triggering or aggravating autoimmune diseases (Rawadi and Roman-Roman, 1998).

Mycoplasmas are able to stimulate as well as suppress lymphocytes in a nonspecific, polyclonal manner, both in vitro and in vivo. Apparently, mycoplasmal B cell mitogens differ from bacterial lipopolysaccarides (LPS) in that they are able to activate lymphocytes from C3H/HeJ mice, which respond poorly to LPS, and their inducing potential is unaffected by polymyxin (Brenner et al., 1997). Modulation of monocyte-macrophage activity by mycoplasmas has been demonstrated in vitro by augmented TNF-α-mediated tumoricidal activity towards different tumor cell lines (Razin et al., 1998). The proven capacity of many mycoplasmas to trigger the production of proinflammatory cytokines in vivo may account for much of the pathology observed during mycoplasma infections and might also influence the subsequent interactions of these microorganisms with lymphoid cells (Manimtim et al., 2001). In addition to affecting various subsets of lymphocytes, mycoplasmas and myco-

plasma-derived cell components modulate the activities of monocytes-macrophages and natural killer (NK) cells and trigger the production of a wide variety of up- and downregulating cytokines and chemokines (Razin et al., 1998; Rawadi and Roman-Roman, 1998). Mycoplasma-mediated secretion of proinflammatory cytokines (such as TNF-α, IL-1 and IL-6) by macrophages and of upregulating cytokines by mitogenically stimulated lymphocytes play a major role in mycoplasma-induced immune modulation and inflammatory responses. On the other hand, the ability of some mycoplasmas to induce downregulating cytokines (such as IL-10, IL-13 and possibly also transforming growth factor [TGF-β]) may contribute to their ability to evade host immune mechanisms by perturbation of macrophage accessory and phagocytic functions. In this way, decreasing production of proinflammatory cytokines and T cell proliferation affect the balance between different T helper cell subsets. The potential to alternately stimulate or suppress the immune system would impart a distinct advantage to any pathogen attempting to survive in the hostile and changing environment of the infected host.

As to the mechanism of cytokine induction by mycoplasmas, Rawadi et al. (1998) reported that protein tyrosine kinase is absolutely required by the *M. fermentans* lipoproteins (LAMPf) to induce proinflammatory cytokines in monocytic cells. The mycoplasmal membrane lipoproteins bind to a cellular receptor(s) that mediates directly or indirectly protein tyrosine kinase activation. This binding triggers the activation of several signal cascade pathways that lead to the phosphorylation and translocation of transcription factors into the nucleus, resulting in transcription and translation of cytokine mRNAs.

Apparently, certain mycoplasmas have more than one cell component with mitogenic activity, and mycoplasmal mitogens are not necessarily identical to mycoplasmal cytokine-inducing elements. *Mycoplasma penetrans* appears to possess several T or B cell mitogens (Brenner et al., 1996; Feng and Lo, 1999), including a glycolipid and a major membrane lipoprotein. However, although the mitogenic *M. penetrans* lipoprotein is also highly immunogenic in *M. penetrans*-positive AIDS patients and elicits production of specific antibodies (Lo, 1992; Brenner et al., 1996), the glycolipid is not recognized in sera of *M. penetrans*-infected individuals.

Of special interest as immunomodulators are the mycoplasmal lipopeptides (MALPs) which resemble the classical murein lipoprotein in that they carry a fatty acid-substituted N-terminal S-(2,3-bis-acyclo-oxypropyl) cysteinyl group but lack the N-acyl long chain fatty acid of the classical bacterial lipoproteins (Muhlradt et al.,1997;

Muhlradt, 2002). This feature renders these mycoplasmal compounds exceptionally active in vitro as macrophage stimulators (Deiters and Muhlradt, 1999). Microgram quantities of the *M. fermentans* MALP-2 were found to stimulate the in vitro as well as in vivo release of chemokines from macrophages, being more potent than LPS on a weight basis (Deiters and Muhlradt, 1999). The co-administration of MALP-2 with a model antigen resulted in potent enhancement of humoral and cellular antigen-specific immune responses, suggesting the use of the lipopeptide as a promising adjuvant for delivery of vaccine antigens (Rharbaoul et al., 2002). Biogenesis of the MALP-2 lipopeptide from the full-length *M. fermentans* lipoprotein MALP-404 involves the extracellular, site-specific proteolytic processing of the lipoprotein yielding the MALP-2 surface-bound lipopeptide as well as a stable, released fragment of MALP-404. This defines a new mechanism of secretion in mycoplasmas and a novel means of altering the phenotype of mycoplasmas through posttranslational processing (Davis and Wise, 2002). Of phylogenetic interest is the finding that the above mycoplasmal lipoproteins share conserved amino acid motifs with lipoproteins of *B. subtilis*, *Treponema pallidum* and the relapsing fever *Borrelia* spp. (Calcutt et al., 1999b; Rosati et al., 1999). In summation, the above data indicate that mycoplasmal lipoproteins and lipopeptides are probably the most relevant mycoplasmal components in the early host reaction. The primary target cells are likely to be the alveolar macrophages liberating chemokines that attract further leukocytes. The MALP-2 mediated response is dependent on the signaling molecules Toll-like receptor 2 (TLR2) and the activation of caspases, inducing apoptosis and cell necrosis (Rawadi, 2000; Luhrmann et al., 2002; Into et al., 2002).

Another chemically defined immunomodulator, produced by *M. arthritidis,* is MAM, a soluble excreted protein of 26kDa acting as a superantigen (reviewed in Cole et al. [2000] and Washburn and Cole [2002]). MAM activates a major fraction of murine T cells and a minor fraction of human T cells by crosslinking MHC class II to TCR, primarily through zinc-dependent binding to the MHC class II E alpha chain in the mouse and to the DR alpha chain in man (Langlois et al., 2003). Activation of T cells (mainly Vβ6 and Vβ8 TCR subsets in mice and Vβ17 and Vβ3 subsets in humans) induces clonal proliferation and release of lymphokines, including IL-2, IL-4, IL-6 and interferon and nitric oxide (Ribero-Dias et al., 2003). Of note is that MAM is the only mycoplasmal superantigen defined thus far. The finding of antibodies to MAM or a portion of the MAM molecule in the sera of rheumatoid arthritis (RA) patients raises

Table 7. Some mycoplasmal cell components active in immunomodulation.

Component	*Mycoplasma*	Biological activity	References
MAM (27-kDa basic protein)	*M. arthritidis*	Superantigen, activating T cells	Cole et al., 2000 Washburn and Cole, 2002
Lipopeptide (MALP)	*M. fermentans*	Activating macrophages, stimulating cytokine and chemokine release (IL-1, IL-6 and TNF-α)	Deiters and Muhlradt, 1999 Muhlradt, 2002
Phosphocholine-containing phosphoglycolipids	*M. fermentans*	Fusogenic agents with cytokine induction activity	Rottem, 2002

Abbreviations: MAM, *M. arthritidis* mitogen; MALP, macrophage-activating lipopeptide; IL, interleukin; and TNF, tumor necrosis factor.

the possibility that MAM or MAM-like epitopes crossreactive with MAM may play a role in RA (Cole et al., 2000), but this clearly requires further study before any definite conclusions can be drawn.

Except for the chemically characterized *M. arthritidis* superantigen MAM, the macrophage-stimulating lipopeptides, and the phosphocholine-containing phosphoglycolipid of *M. fermentans* (Table 7), cell components exhibiting mitogenic and cytokine-inducing activities from the other mycoplasmas need to be identified and isolated. Likewise, there is very little information on the nature of host cell receptors for the mycoplasmal immune modulators.

Applications

The theoretical contributions derived from the application of mycoplasmas as effective research models applied to solve basic problems in biology, including biomembrane and genomic research, have been discussed at length in many sections of this chapter. On the technological side, most of the applications emanating from the molecular biology and genetic research of mycoplasmas concern the development of diagnostic kits and DNA vaccines, described in preceding sections of this chapter. While discussing biotechnological applications, mention should be made of a negative aspect resulting from the frequent troublesome infection of cell cultures by mycoplasmas (see the section Habitats and Ecology). According to regulations of the United States Food and Drug Administration, every biological product produced in cell cultures should be tested for the presence of mycoplasmas, an expensive step that cannot and should not be avoided.

The high cost of mycoplasma cultivation and low yields of organisms do not encourage their use as a source for production of biochemicals, unless the material is unique. This seems to be the case for the peculiar DNA methylase produced by *Spiroplasma monobiae* (MQ-1). The enzyme was found in our laboratory (Nur et al., 1985) to methylate all cytosine residues located at the sequence cytosine-guanine, the only sequence methylated in eukaryotic DNA. To exploit this finding, the methylase gene of the spiroplasma was cloned, and a special system was developed to express it in *E. coli* to overcome the UGA problem (see the section Codon Usage). Expression in *E. coli* could be used to produce large quantities of the enzyme on a commercial basis needed as a research reagent in laboratories working on eukaryotic DNA methylation.

CHAPTER 1.2.30

The Phytopathogenic Spiroplasmas

JACQUELINE FLETCHER, ULRICH MELCHER AND ASTRI WAYADANDE

Introduction

Spiroplasmas (family Spiroplasmataceae, order Mycoplasmatales) comprise a group of helical prokaryotes whose external morphology, unlike that of the spirochetes, is defined by an internal skeletal framework rather than by an external peptidoglycan-containing cell wall. The loss of a cell wall in mollicutes (spiroplasmas, mycoplasmas, phytoplasmas, acholeplasmas and others) is due to degenerative evolution from their walled precursors (see also The Phytopathogenic Spiroplasma in this Volume, which provides extensive coverage of this taxon). Most of the more than 50 spiroplasma species that have been described are associated with insects and other animals in relationships that range from pathogenic to benign. For example, *Spiroplasma melliferum* infects honeybees (Whitcomb and Williamson, 1979), other spiroplasmas cause disease in mosquitoes (Humphery-Smith et al., 1991), and the "sex ratio" spiroplasma kills the male progeny of fruit flies (Williamson et al., 1989). Many spiroplasmas, however, colonize the gut lumen and/or hemolymph of their insect hosts without causing detrimental effects (Whitcomb and Williamson, 1979). Only three species of spiroplasmas (*S. citri*, *S. kunkelii* and *S. phoeniceum*) are known to cause disease in plants. These microbes are important for two reasons. First, they cause significant losses in economically important crops such as maize (corn stunt disease) and citrus (citrus stubborn disease), and in specialty crops (brittle root of horseradish). Second, and perhaps just as important, the plant pathogenic spiroplasmas, which are cultivable in artificial media, serve as models for the more numerous, widespread, and noncultivable phytoplasmas, a group of related mollicutes that cause disease in over 300 plant species globally. In this chapter, the focus is on the unique features and issues related to the small, but economically important, group of spiroplasmas that cause diseases in plant hosts.

Historical Background

For many years, the diseases citrus stubborn and corn stunt were attributed to viral etiology, as their agents were graft transmissible and could not be cultivated. Remission of symptoms in stubborn diseased citrus trees following application of tetracyclines, but not penicillin (Igwegbe and Calavan, 1970), suggested that a nonviral agent might be involved. But a novel microbial taxon was not recognized until the late 1960s when thin sections of maize displaying strong symptoms of a long-known, economically serious stunting and yellowing disease called "corn stunt" were examined by electron microscopy (Davis and Worley, 1973). The unusual prokaryotes visualized in those sections (later designated "spiroplasmas") were smaller than most bacteria and had a distinctive helical morphology and lacked the peptidoglycan-rich outer wall that defines most prokaryotes.

Morphology

The first descriptions of the morphology of spiroplasmas were made by Davis and colleagues (Davis et al., 1972; Davis et al., 1973), who used phase optics to view sap expressed from corn plants with symptoms of corn stunt disease. They described the associated microbes as helical filaments about 3–15 μm long and 200–250 nm in diameter with a regular wave (gyre) length and an amplitude of 0.4 μm. Later designated "*S. kunkelii*," this microbe was recognized as a new taxon. An early description of *S. citri* indicated that it was somewhat larger at 410–500 nm diameter (Liu, 1981). Some helical spiroplasmas were accompanied by spherical bodies of 400–600 nm diameter (Davis and Worley, 1973; De Leeuw et al., 1985); when grown on agar for several days, older spiroplasmas became elongated, branched, and even appeared to split into beaded chains (De Leeuw et al., 1985). With electron microscopy the spiroplasma outer membrane was

clearly free from a surrounding wall and organized as a single triple-layered unit whose thickness ranged from about 7.0–7.5 to about 10 nm (Davis and Worley, 1973; Liu, 1981). The presence of cholesterol in spiroplasma membranes, an unusual feature in bacteria, presumably adds rigidity to this structure. No visible flagella or other structures that could explain the observed motility were found. The two termini of the spiroplasma helix are usually different, one being rounded or blunt and the other narrowing to a point (Garnier et al., 1981). A recent electron microscopy study by Ammar et al. (2004) provided new details on spiroplasma morphology. Helix lengths of four spiroplasma species (the plant pathogens *S. citri* and *S. kunkelii* and the non-phytopathogens *S. floricola* and *S. melliferum*) varied among the species. A globular section was often seen at one end, and small rounded structures (possibly the same as the "spherical bodies" described earlier by Davis and colleagues) appeared to bud from the main helix.

Spiroplasmas grown in culture may occur in clusters or groups. Townsend et al. (1980) described commonly occurring "medusa-like aggregates" of helical filaments extending from a central point. Such aggregates apparently result from a failure of spiroplasmas to separate following cell division.

How spiroplasmas maintain their unique helical morphology (Fig. 1) in the absence of a cell wall, such as that of spirochaetes, and how they move in the variety of ways observed without visible motility-related appendages such as flagella, were questions of great interest in the early days of spiroplasma characterization. Internal fibrils were observed in several spiroplasma species, including the plant pathogen *S. citri,* using various electron microscopic and other

strategies (Cole et al., 1973; Williamson and Whitcomb, 1974b; Williamson et al., 1974; Razin, 1978; Stalheim et al., 1980; Townsend et al., 1980; Charbonneau and Ghiorse, 1984), and actin-like proteins were identified in several strains of *S. citri* (Kirchoff, 1992). Taking advantage of recent technological advances, Trachtenberg and colleagues (Trachtenberg et al., 1987; Trachtenberg et al., 2003; Trachtenberg, 1998; Trachtenberg and Gilad, 2001) have provided a more complete understanding of spiroplasma morphology. The picture emerging is that of the spiroplasma cell as a tubular structure, inside which a flat ribbon, about 940 Å wide and composed of parallel fibrils, each 45–50 Å in diameter, is attached along its length to the tube's inner wall (the cell membrane). Tube and ribbon together assume a helical shape such that the ribbon extends down the shortest side of the tube. The major fibril protein, encoded by the *fib* gene (Williamson et al., 1991), probably consists of a tetramer of 59-kDa monomers. Multiple tetramers associate to form the fibrils, and seven fibrils adjoin in a single flat ribbon (Trachtenberg and Gilad, 2001). Fibrils in different spiroplasma species are similar, as demonstrated by the reaction of antibodies made against *S. melliferum* BC3 fibrils with fibrils from 13 other groups (Townsend and Archer, 1983). The fibrillar skeleton has been suggested to function like a linear motor, in which coordinated shortening and lengthening caused by conformational changes in the tetramer proteins determine shape and motion (Trachtenberg and Gilad, 2001).

Some mycoplasma pathogens of animals and humans have been described as flask-shaped, with the "neck" of the flask comprising an attachment organelle (tip structure) involved in adherence. Liu and colleagues (Liu, 1981; Liu et al., 1983) described a long, thin, electron-dense neck for *S. citri* cells during their residence in the intestinal tract of the leafhopper vector, *Circulifer tenellus*, and postulated that it might aid in penetration of the endoplasmic reticulum, with which these authors often found spiroplasmas associated. Phillips and Humphery-Smith (1995), studying a mosquito-pathogenic spiroplasma, *S. taiwanense,* also described maturing spiroplasmas as pleomorphic and presented transmission electron micrographs showing rounded cells with narrower extensions consistent with a neck structure. Recent ultrastructural studies of *S. kunkelii* were consistent with Liu's and Humphery-Smith's observations; Ammar et al. (2004) and Ozbek et al. (2003) reported that the cores of the *S. kunkelii* helix termini (the pointed or rounded ends that result following cell division) were more electron-dense than those of the central regions of the cell. *Spiroplasma kunkelii* cells consistently aligned themselves tip-down among

the midgut microvilli, and the penetration of the tips within the lamina densa suggested a role for the tip structure in adhesion, similar to that of the attachment organelles of animal pathogenic mycoplasmas, and in traversal of the basal lamina, a specialized extracellular matrix (containing laminin, nidogen and collagen; Sreebny, 1988) that functions as a selective barrier and plays a role in regulating various cell functions. *Spiroplasma citri* cells also attach via their ends to the lumen-side surface of gut epithelial cells prior to invasion (Kwon et al., 1999), but morphologically distinct tip structures were not observed in that study (A. Wayadande and J. Fletcher, unpublished observations). As with zoopathogenic mycoplasmas, a flask-shaped tip could contribute to another type of spiroplasma motility, termed "gliding," in which the cells travel in the direction of their tips.

Although helical cell morphology is one of the most distinctive features of spiroplasmas during their life in the plant and also in medium, it is not always maintained in the alternate host/insect vector. Townsend et al. (1977) noted that immediately after microinjection into the hemolymph of the experimental leafhopper vector, *Euscelidius variegatus*, many helical cells of *S. citri* could be seen by electron microscopy, but over the period of a week, the helices gradually disappeared and were replaced by tiny, pleomorphic bodies. Loss of helicity in the insect was noted also by Liu (1981), who described *S. citri* cells in the vector *C. tenellus* as consisting of a main body with a long, thin, electron-dense branch, and by Kwon et al. (1999). Interestingly, although *S. kunkelii* apparently loses helicity in its vector, the corn leafhopper *Dalbulus maidis* (Granados and Meehan, 1975), it remains helical in other leafhopper species including *D. elimatus* and *E. variegatus* (Markham et al., 1977). That spiroplasmas could be cultivated from such hemolymph despite the absence of helical cells supported the conclusion that the pleomorphic bodies were, in fact, viable spiroplasmas. In a natural setting, spiroplasmas reach the hemocoel of their insect vectors only after traversal of the gut wall. In such cases the loss of helicity may occur before the microbes reach the hemocoel. In recent work (Ozbek et al., 2003; Ammar et al., 2004), cross sections of *S. kunkelii* cells that had invaded midgut epithelial cells were examined; spiroplasmas located near the gut lumen side of the epithelial cell were of normal size while those residing on the hemolymph side of the epithelial cell were significantly larger, suggesting that the change from a helical to a pleomorphic morphology occurred during the journey across the epithelial cell cytoplasm.

Recent transmission electron microscopy (Ozbek et al., 2003) of *S. kunkelii* cells within the bodies of *D. maidis* revealed surface appendages interpreted as fimbriae and pili. The former structures are long, narrow (10–12 × 211–1555 nm) organelles that, in other bacteria, contribute to adherence (to host cells or to other bacteria) and also may participate in cell signaling. The apparent contact between the *S. kunkelii* fimbriae, arranged peritrichously, and the vector insect's gut epithelial and muscle cell outer surfaces is consistent with the concept of a similar role in attachment for spiroplasma fimbriae. Indeed, the authors suggest roles for them also in detachment of host cell laminae from the underlying cell layer and prevention of host cell apoptosis. Shorter, polar-located filaments resembling type IV pili of many other bacteria also were described in *S. kunkelii* (Ozbek et al., 2003; Ammar et al., 2004; Bai et al., 2004). Type IV pili contribute to many cell functions including "twitching" motility, transformation, virus infection, biofilm formation, activation of host responses and bacterial conjugation. Proteins of the traE group are commonly implicated in pilus formation; interestingly, four *traE* genes recently have been identified in *S. kunkelii* (Bai et al., 2004). Other surface-associated structures include rod-shaped spiroplasma viruses (Fig. 2), approximately 230–280 by 10–15 μm in size (Bové et al., 1989). Viruses, too, adhere at their tips, perpendicularly, to the mollicute membrane (Townsend et al., 1977; Sha et al., 1993), such that the particles may appear very similar to those structures described as pili or fimbriae.

When diluted suspensions of spiroplasmas are spread onto the surface of appropriate agar-solidified media they produce slow-growing colonies. Although mycoplasmas are known for their distinctive "fried egg" colony morphology, spiroplasmas colonies typically are not so described. Their tiny colonies are usually characterized by indistinct edges resulting from a halo of satellite colonies, produced by spiroplasmas

that have traveled through the pores in the medium (Fig. 3).

Motility

Davis and Worley (1973) described spiroplasmas as cells that "whirled or spun rapidly about the long axis" and exhibited distinctive "vermiform" movements including flexing, folding and curling as well as contractile movements that progressed in a wave from one end of the cell to the other. Motility is greatest when spiroplasmas are grown under optimal conditions. In dense substrates spiroplasmas also display translational movement and are sensitive to chemical gradients, responding to various compounds with either positive or negative chemotaxis (Daniels et al., 1980). The role of motility in colonization of host tissues in the plant or insect vector is not well understood, but it may be a factor in the accumulation of spiroplasmas in growing plant terminals and in the salivary glands of insects.

Loss of helicity and motility seems to occur naturally at a low rate. A naturally-occurring nonhelical and nonmotile strain, ASP-1, of *S. citri* was isolated serendipitously within a population of normally helical cells from "little-leaf" affected orange trees (Townsend et al., 1977). The novelty of the strain was recognized initially by the unusual colony morphology. The lack of normal motility (ASP-1 cells displayed only a movement described as "twitching") resulted in colonies having sharply defined edges. Protein profiles revealed the absence, in ASP-1, of a single polypeptide of 39 kDa. Neither the protein, nor the helicity and motility, were necessary for pathogenicity, as the natural mutants produced symptoms indistinguishable from those of wildtype following the confinement of ASP-1-injected leafhoppers onto test plants. A few years later, Lee and Davis (1987) isolated several nat-

urally occurring variants of *S. kunkelii* having varying degrees of defects in helicity and motility. One strain having normal helical cells displayed little or no motility, indicating that the two features were independent of one another.

Recently, motility of *S. citri* strain GII3 was interrupted by Tn*4001* mutagenesis (Foissac et al., 1997). The inactivated gene, identified and designated "*scm1*," could be complemented with the wildtype gene (Jacob et al., 1997), suggesting a critical role for the *scm* gene product in spiroplasma motility.

Cell Division

As far as is known (see The Genus Spiroplasma in the second edition) the general outlines of cell division of phytopathogenic spiroplasmas are the same as those of other mollicutes. However, because spiroplasma morphology is different from that of other mollicutes there are some unique aspects. For example, the helicity of spiroplasmas provides a simple meter stick by which to measure length requirements for division. Garnier et al. (1981) reported that the minimum length of *S. citri* cells grown in culture was two complete helices. In an actively growing culture, cell division occurred by constriction near the center, usually of spiroplasmas having four complete turns, so that both products of division would be of the minimal size. Growth at higher temperatures (37°C) prevents cell division, resulting in elongated cells consisting of multiple turns.

Growth is necessary for cell division. Where that growth occurs is difficult to assess because of conflicting results (Garnier et al., 1984). Antibody labeling suggests that growth of the membrane is diffuse throughout the length of the cell. However, labeling with tritiated amino acids or of redox sites with tellurite suggests polar growth.

Models accounting for cell shape based on the structure and activity of fibril protein-containing structures invoke a role for the structures in DNA segregation (Townsend, 1983). Such fibril-composed structures, and their roles in spiroplasma morphology, have been more completely described in recent work (Trachtenberg et al., 1987; Trachtenberg, 1998; Trachtenberg and Gilad, 2001; Trachtenberg et al., 2003; see the section Motility above in this Chapter).

Zhao et al. (2004), working from the genome sequence of *S. kunkelii* (see the section Strains, Species and Taxonomic groups below in this Chapter) have identified homologues for *ftsZ* and *ftsA* genes in this phytopathogen. The former, in other bacteria, is known to be responsible for the formation of the septum between the two daughter cells.

Phylogeny and Taxonomy

Only three species of plant pathogenic spiroplasmas have been identified to date. New species of spiroplasmas are still being discovered and proposed. However, the rate of discovery is far less than originally predicted from the observation that one in ten species of arthropod examined contained a hitherto undescribed spiroplasma (Hackett and Clark, 1989). Many species have since been identified that are found in, and can grow in, multiple arthropod species. Thus, the *Spiroplasma* species is unlikely to be the most speciose on earth (Gasparich, 2002). Nevertheless, apparently novel species are still being described (Fukatsu et al., 2001), which makes it likely that more than the approximately 50 spiroplasma species known today will eventually be recognized. On the other hand, that all three plant pathogenic species were identified early during the exploration of the genus suggests that there may not be many additional plant pathogenic species.

Strains, Species and Taxonomic Groups

Partial serological crossreaction placed the three phytopathogenic spiroplasmas in group I, with five others (Gasparich, 2002). Each of the three constitutes a separate subgroup within the group: subgroups I-1, I-3 and I-8 corresponding, respectively, to *S. citri*, *S. kunkelii* and *S. phoeniceum*. Phylogenetic differentiation below the subgroup level has been reported between Old World and New World *S. citri* (Igwegbe et al., 1979). The subgroups were established according to the rule that reciprocal DNA-DNA hybridization experiments reveal only 30–70% crossreactivity (Gasparich, 2002). For example, less than 55% crossreaction was observed between *S. citri* and *S. kunkelii* (Lee and Davis, 1980). The 70% crossreactivity value has also been established as the minimum between isolates of bacterial species. Thus, the subgroup designation is equivalent to the species designation. Protein profiles also differentiate group I spiroplasmas into subgroups (Mouches et al., 1982); for example, distinguishing *S. citri* from *S. kunkelii*. Differentiation based on protein profiles, however, is less definitive for other subgroups (Mouches et al., 1983b).

The less than 70% reciprocal DNA-DNA hybridization measuring stick for classification of a pair of isolates into separate species has two theoretical components: the fraction of sequence in one isolate that has homologous sequence in the other and the fraction of that DNA that has retained sufficient nucleotide sequence identity to form stable hybrids with its homolog. The hybridization value does not measure directly the degree of sequence divergence. The availability of sequences of gene-rich regions from both *S. citri* and *S. kunkelii*, however, allows direct estimation of the degree of divergence between the two genomes (U. Melcher and J. Fletcher, unpublished observation). In 39 kbp of compared sequence, only 7.3% was too far diverged to be recognized as homologous. Of the remaining sequence positions, an average of 93.3% (range 88–95%) had identical nucleotides. The high percentage identity should be sufficient to form stable hybrids if hybridization is performed at 15 or more degrees below the melting temperature.

Resolution of the apparent conflict between the close identity in nucleotide sequence for the selected genes and the less than 55% cross-hybridization value should be resolved when genome sequence information for the two spiroplasmas is available. Although a project to sequence the genome of *S. citri* GII3 has been underway (Foissac et al., 2004), the sequence is not yet publicly available. In a different initiative, the *S. kunkelii* genome sequence was almost completely sequenced and the information is posted (http://www.genome.ou.edu/spiro.html {Spiroplasma kunkelii Strain CR2-3x Genome Sequencing Web site}) but not yet fully annotated. Nevertheless, some guesses can be made. Most of the genes contributing to the analysis encode enzymatic proteins essential for the survival of these spiroplasmas in the environment in which they thrive. They are thus under strong negative selection, so that only rare changes are expected. On the other hand, the *spi* genes, encoding a nonenzymatic major surface protein, are known to vary more substantially, even undergoing positive selection for amino acid changes (Foissac et al., 1996; Melcher and Fletcher, 1999a). Thus, a comparison of *spi* nucleotide sequence conservation between *S. citri* and *S. kunkelii* reveals only 84.7% identity with only 68% coverage of the gene. This level is likely too low to produce DNA-DNA cross-hybridization. For comparison, conservation of *spi* between *S. citri* strains is 97–99%, with complete or close to complete coverage. One possible extrapolation of these findings is that the genomes of *S. citri* and *S. kunkelii* consist of no more than 60% of conserved genes, the "core" genome (Hacker and Carniel, 2001) necessary for essential enzymatic functions, and about 40% of highly variable genes, the "flexible" genome, probably encoding surface proteins that interact with the environments of the spiroplasma. An alternate possibility, that *S. citri* and *S. kunkelii* have different complements of mobile genetic elements, is discounted by the observation that the elements frequently encountered in *S. citri*

are also the most frequently found in the *S. kunkelii* genome, accounting for as much as 18% of the genome.

Host Associations

The other five members of group I are not known to be associated with plant disease, though most have some association with plants. For most spiroplasmas, this association is an external one, with the organisms being found in places such as nectaries and leaf and flower surfaces. Plant association is not a unique property of group I spiroplasmas, nor are they associated preferentially with one kind of arthropod; leafhoppers, honeybees, ticks, fruit flies and beetles are among the animal hosts (Gasparich, 2002). Yet, only group I has phytopathogenic members, suggesting that the group has acquired or developed a gene or gene systems allowing colonization of plant interiors. The plant contact could have provided the theater for phytopathogenicity to evolve separately three times in this group. Alternatively, *S. citri*, *S. kunkelii* and *S. phoeniceum* could have derived from a phytopathogenic common ancestor not shared by other group I species.

Evidence suggests that plant pathogenicity did not simply arise once in the common ancestor of the three spiroplasma phytopathogens. In this regard, 16S rDNA sequences are uninformative since the *S. phoeniceum* sequence is missing and identities between the others (98–99%) are too close to be sure of the significance of differences. Though five phylogenetically informative positions cluster *S. kunkelii*, *S. citri* and *S. melliferum* (the latter of which is non-phytopathogenic), only one each suggests that the first two and the last two are closer to one another. Fortunately, the more diverged *spi* gene provides good support for sister status for *S. citri* with *S. melliferum* and for *S. kunkelii* with *S. phoeniceum*. The former pair is 94.2% identical over 99% of their common length and the second pair is 92.6% identical over 98% of the length, as opposed to the much lower cross-pair values for *S. citri* and *S. kunkelii* mentioned above. This result suggests an initial divergence of clades containing an *S. citri-melliferum* ancestor and an *S. kunkelii-phoeniceum* ancestor. In this scenario, plant pathogenicity may have arisen twice, once before the *S. kunkelii-phoeniceum* divergence and once after the *S. citri-melliferum* divergence. Alternatively, both ancestors may have been phytopathogens, with this trait later being lost from *S. melliferum*. Also possible is that pathogenicity of the latter exists but has just not been documented.

Spiroplasma Position Among Mollicutes

To address the question of whether plant pathogenicity may have arisen in other spiroplasma lineages, it is important to review current understanding of Mollicutes evolution (Weisburg et al., 1989; Maniloff, 1992; Williamson et al., 1998; Gasparich, 2002; Gasparich et al., 2004). Early theories that mollicutes were the result of degeneration of L-forms of many different bacteria, or that mollicutes were the ancestors of walled bacteria have been largely discounted. Nevertheless, there is some support for these views. The mollicute *Asteroleplasma anaerobium* appears to be more closely related to genera of Gram-negative bacteria than to other mollicutes (Weisburg, 1989). This observation suggests the Mollicutes class is phylogenetically polyphyletic. Support for a mollicute origin for some walled bacteria is provided by the observation that the *S. citri dnaA* gene, which functions in DNA replication, is more distant from those of *S. apis* and *M. mycoides* than *dnaA* genes of walled bacteria are from one another (Suzuki et al., 1993). The observation suggests that divergence began in the walled bacteria much more recently than in the mollicutes. Longer branches on mollicute lineages than on lineages of other bacteria were also noted in a study of concatenated sets of more than 50 proteins present in all bacteria (Zhao et al., 2004), including phytoplasmas, but were interpreted to mean that evolution was more rapid in the mollicutes. The new concatenated protein study is consistent with the currently accepted view of *Mollicutes* evolution based primarily on 16S rDNA sequences (Woese et al., 1980). Relationships deduced from other genes, such as 5S rDNA (Walker, 1983), *dnaA* (Suzuki et al., 1993), and *pgk*, encoding phosphoglycerate kinase (Wolf et al., 2004), have provided supporting information.

The class is thought to have arisen by degenerative evolution from walled bacterial ancestors, as judged from nucleotide sequence (Woese et al., 1980) and lipid composition (Langworthy, 1983). In one scenario (Maniloff, 2002), birth of the class occurred around 605 million years ago (Mya), coincident with a major expansion in the diversity of marine animal life. About 470 Mya, about the time the first land plants appeared, the ancestral lineage split into two clades, one containing the *Acholeplasma*, *Aneroplasma* and phytoplasmas and the other composed of *Mycoplasma*, *Entomoplasma*, *Mesoplasma* and *Spiroplasma*. Phytoplasmas have to date not been cultured in vitro but are phytopathogens, indicating that plant pathogenicity has evolved at least twice among mollicutes. About 410 Mya, when the first land animals appeared and there was another major marine expansion, a split

occurred that led to the establishment of a major clade of *Mycoplasma*. The other branch led to the *Spiroplasma*, *Entomoplasma*, *Mesoplasma* and another clade of *Mycoplasma*, the mycoides cluster. A study of the progression of the numbers of lineages over time (Maniloff, 2002) led to the observation that *Mycoplasma* experienced a radiation into a variety of lineages about 191 Mya and that a similar radiation occurred for *Spiroplasma* about 100 Mya. Maniloff (2002) thought these events correspond well to the appearance of the first mammals and other vertebrates and to the radiation of flowering plants and their associated insects, respectively.

Phylogeny vs. Taxonomy

The phylogenetic patterns in these genera do not mirror the taxonomic groupings of organisms. The groupings had been based on a variety of phenotypic characters including absence of a cell wall, mol% G+C content of the DNA, genome size, sterol requirements, and other metabolic characteristics (Gasparich, 2002; Gasparich et al., 2004). The existence of two *Mycoplasma* clades means that this genus is not monophyletic. The pattern of *Spiroplasma* evolution is such that some lineages of this species had diverged before the cluster of *Entomoplasma* and *Mesoplasma* diverged from one of these lineages. As a result, this genus also is not monophyletic. A similar statement can be made for the *Entomoplasma* and *Mesoplasma* since the mycoides cluster diverged from a branch of this group of genera. As more and more sequences were obtained, more and more discrepancies between taxonomy and phylogeny became apparent.

The Big Picture

The picture to emerge from these phylogenetic considerations is that, if one were able to trace back the biogeographical niches of all the ancestors of any extant spiroplasma, one would find the lineage to be highly cosmopolitan, having spent time during its evolution in association with a variety of arthropod species, being deposited on or in a variety of higher plants and even occasionally becoming associated with vertebrate species. Often when an organism switches its host association, it initially causes disease in the new host. After a period of mutual adaptation, the pathogenicity is lessened until the relationship is one of commensality if not of mutualism. Thus phytopathogenicity may have arisen and disappeared multiple times during the evolution of spiroplasmas. However, as mentioned in the Introduction above, currently, only three phytopathogenic species are known.

Habitat

Plant Host Range and Specificity

Phytopathogenic spiroplasmas colonize the host plant's phloem sieve tubes, the tissue responsible for translocation of photosynthates from chlorophyllous photosynthetic tissues to metabolic sinks such as flowers, fruits, newly expanding leaves and storage organs. Although they are demanding in their growth requirements (and therefore dubbed "fastidious prokaryotes") spiroplasmas also colonize a second habitat that is very different from plant phloem—the hemolymph of insects in the Homoptera that transmit them from plant to plant (see the section Insect Transmission below in this Chapter). Although phloem sieve tubes and insect hemolymph share certain important features, both being rich in nutrients and serving as the transport for delivery of these compounds to other tissues, it is reasonable to hypothesize that colonization of these two ecological niches require different adaptations. Strong current interest in identifying genes differentially expressed in different environments will certainly contribute to our understanding of these microbes' ability to colonize different host tissues and to adapt rapidly as they shuttle between their plant and insect hosts.

CORN STUNT. The first reported observation of corn stunt was in 1942, when it was described in California's San Joaquin Valley (Stoner and Ullstrup, 1964). Three years later, the disease was diagnosed in South Texas, and reports followed from Mexico, Central and South America, all the states of the United States bordering Mexico, countries of the Caribbean Sea, and several Corn Belt states. The corn stunt spiroplasma also infects *Zea mays mexicana* and *Z. diploperennis*, *Z. perennis*, *Z. mays* X *Tripsacum floridanum*, and *Z. luxurians* (Nault, 1980). Experimental plant hosts include a range of monocotyledonous and dicotyledonous species; leafhoppers whose normal host range includes these species and that have been injected with the corn stunt spiroplasma can be used as a vehicle of infection.

The term "corn stunt" was used early on to describe a series of syndromes that later became distinguishable as different diseases caused by different pathogens or combinations of pathogens including *S. kunkelii*, the maize bushy stunt phytoplasma, and at least two viruses, maize chlorotic dwarf virus and maize rayado fino virus (Nault and Bradfute, 1979). Symptoms and impacts of *S. kunkelii* infection are described in the section Symptoms.

CITRUS STUBBORN. Citrus stubborn disease was first reported in California navel orange trees in 1915. The name "stubborn" was coined by citrus growers whose best efforts to cure their

trees were unsuccessful (Calavan and Oldfield, 1979). In 1928, the disease was discovered in several Mediterranean countries (being designated "little leaf" in Israel). It is now known to occur in most hot, dry citrus-growing areas around the globe but does not appear to be a serious problem in cool or humid areas. In contrast to *S. kunkelii*, *S. citri* (the citrus stubborn agent) is a generalist with a relatively broad host range. All citrus varieties grown in California are susceptible, but grapefruits, tangelos, and navel and Valencia oranges are particularly affected. Calavan and Oldfield (1979) identified natural infections in *Brassica tournefortii,* London rocket, pansy, rutabaga, turnip, wild radish, and wooly plantain. Later studies implicated other natural hosts and a large number of artificial ones. Although most are dicotyledonous, the pathogen also infects a few monocots, including onion. Symptomatology is described in the section Symptoms.

HORSERADISH BRITTLE ROOT. Although an unexplained disease of the southern Illinois specialty crop, horseradish (*Armoracea rusticana*), had baffled producers for a number of years, the sporadic nature of serious epidemics had hampered investigations into its cause. In 1984, a serious epidemic prompted investigation into the causal agent. Initially thought to be of viral etiology, the disease was found to be caused instead by the mollicute *S. citri* (Fletcher et al., 1981; Raju et al., 1981b). In epidemic years, some fields can be complete losses. Although *S. citri* already was known to infect a significant number of Brassicaceous species in California, the 1984 outbreak in Illinois horseradish was remarkable in its severe impact on the crop and its geographical distance from other known *S. citri* locations (Fletcher et al., 1983). Two years later, the same disease was found in horseradish plantings in Maryland (Davis and Fletcher, 1983). In Illinois, the spiroplasma often occurred in horseradish in mixed infections with viruses (Fletcher et al., 1984a) or with a phytoplasma (Eastman et al., 1984). Symptomatology is described in the section Symptoms.

Insect Host Range and Specificity

Although spiroplasmas have been isolated from most insect orders examined to date (Gasparich et al., 2004), transmission of plant pathogenic spiroplasmas has thus far been limited to leafhoppers (Order Hemiptera: suborder Homoptera: family Cicadellidae). Leafhopper vectors of spiroplasmas fall into a single taxon, the subfamily Deltocephalinae. Deltocephaline leafhoppers account for the majority of vectors of all leafhopper-transmitted pathogens, including leafhopper-borne viruses and phytoplasmas. This group of insects has been particularly well studied and has vector species in several tribes that make up the Deltocephalinae. The competent vectors of *S. kunkelii* include macrosteline leafhoppers *Dalbulus maidis* (Fig. 4) and *D. elimatus*. Other members of the genus are less efficient or nonvectors. Experimental vectors of *S. kunkelii* include *Cicadulina mbila* (the vector of maize streak virus), *Macrosteles sexnotatus*, *Graminella nigrifrons* (the vector of several maize viruses), *Stirellus bicolor*, *Euscelidius variegatus* and *Exitianus exitiosus*. The likelihood that any of these experimental vectors could be competent field vectors of *S. kunkelii* is low, with the possible exception of *C. mbila*. This species, a serious pest of maize and the primary maize streak virus vector, transmits the spiroplasma at 60% efficiency when given access to infected maize plants (Markham and Alivizatos, 1983b). Introduction of *S. kunkelii* into regions of Africa where *C. mbila*-maize systems are prominent could facilitate establishment of *S. kunkelii* on the African continent.

Leafhopper vectors of *S. citri* include *Circulifer tenellus* (Fig. 4), *C. haematoceps* (synonyms: *Neoaliturus tenellus* and *N. haematoceps*), *Scaphytopius nitridus* and *S. acutus delongi*. The host range of *S. citri* roughly coincides with the geographical distribution of *Circulifer* leafhoppers to include North America, the Mediterranean region, Africa, and Asia (Klein, 1992).

The degree of transmission specificity for both *S. citri* and *S. kunkelii* is high among the relatively small group of vectors for each pathogen (Table 1). This observed specificity of vector competency is primarily determined by vector host plant range. The *Circulifer* leafhoppers are polyphagous, feeding and reproducing primarily on dicotyledonous plants, including cruciferous hosts of *S. citri* (Cook, 1967). Interestingly, the economically important *S. citri* plant host, citrus, is not a preferred feeding and reproductive host of *Circulifer* leafhoppers, acquisition likely occurring from alternate weed hosts (Oldfield, 1988). The *S. kunkelii* vectors within the genus *Dalbulus* are specialists of either *Zea* spp. or *Tripsacum* spp. (Nault, 1990). *Dalbulus* leafhoppers are unlikely to feed on *S. citri* host plants, although the ability to feed and survive on phytoplasma-infected periwinkle was documented for *D. maidis* (Purcell, 1988). Similarly, the *S. kunkelii* plant host, maize, is unlikely to attract and support *Circulifer* spp.

Isolation and Cultivation

Cultivation

Spiroplasmas vary considerably in their adaptability to artificial media. In 1971, *S. citri* became the first spiroplasma, and the first phytopathogenic mollicute, to be cultivated in vitro when two research groups independently reported success using relatively simple media adapted from mycoplasma cultivation (Saglio et al., 1971; Fudl-Allah et al., 1972). The subsequent cultivation of *S. kunkelii* proved to be more challenging, however, because *S. kunkelii* failed to grow in media that supported rapid growth of *S. citri*, suggesting that the growth requirements of these two close relatives were different. By 1975, however, Chen and Liao (1975) succeeded in cultivating *S. kunkelii* using a relatively simple medium, while Williamson and Whitcomb (1975) achieved *S. kunkelii* cultivation by adapting formulations used for cultivation of *Drosophila* tissue cultures. Most spiroplasma media are relatively complex, chemically undefined mixtures (Chen and Davis, 1979; Lee et al., 2001). Animal sera are frequently used as a source of required cholesterol, an essential component of spiroplasma membranes, and undefined components such as yeast extract also are common. Also included are organic acids, amino acids, fatty acids, sugars,

inorganic salts and buffers. Recipes for a number of spiroplasma media are provided by Chen and Davis (1979), Liao and Chen (1982), Bové et al. (1983), Whitcomb (1983), and Lee et al. (2001).

Since the absence of a cell wall renders spiroplasmas vulnerable to osmotic lysis, successful ultivation has required the optimization of the osmotic pressure of culture media. Initial attempts were made to re-create the osmotic pressure within a sieve tube element, the phytopathogenic spiroplasmas' natural environment. Saglio et al. (1972) added both sucrose and sorbitol to their broth medium; the former as a carbon source and the latter to maintain an osmotic pressure of about 15 atm. The specific nature of the osmoticum may be important. High concentrations of sorbitol proved to be inhibitory for the growth of *S. kunkelii,* which grew much better at sorbitol concentrations about a third of those optimal for *S. citri* growth (Chen and Davis, 1979).

Temperature, pH and oxygen concentration are important factors in the growth of spiroplasmas. Most plant-associated spiroplasmas grow best at 30–32°C (Konai et al., 1992), their growth rates falling dramatically at warmer or cooler temperatures, while spiroplasmas from mammals can tolerate much higher temperatures (Chen and Davis, 1979). The optimal pH for most common spiroplasma media is 7.0–7.8. Higher or lower pH levels not only change the spiroplasmas' growth rate but also the highest titer reached and even the cell morphology (Chen and Davis, 1979). Changes in cell shape occur as a spiroplasma culture ages and acidic byproducts of metabolism accumulate, lowering the pH. While *S. citri* cultures are normally isolated and maintained in aerobic conditions, the corn stunt agent was isolated at higher frequency, and achieved a higher titer, when incubated in an anaerobic atmosphere with 5% CO_2 (Davis et al., 1984).

Isolation from Host Tissues

Initial isolation of spiroplasmas from infected plant tissue into artificial media presents challenges (Liao and Chen, 1982; Bové et al., 1983; Lee et al., 2001). Contamination by epiphytic microorganisms, whose growth rates are likely to far exceed those of the "fastidious" spiroplasmas, may be reduced by surface sterilization or by removal of the plant epidermis prior to sampling from the interior region. Samples are placed into a small volume (3–5 ml) of buffer or medium of suitable osmolarity and minced to increase the surface area from which spiroplasmas exude. During a short (5–10 min) incubation period at room temperature, spiroplasmas respond chemotactically, swimming out of the tissue into the sugar-rich medium. The medium-plus-

spiroplasma suspension is filtered (0.45 μm) to eliminate walled bacteria, fungal spores and plant debris. Because extracts from many plant species or tissues contain substances that inhibit spiroplasma growth (Liao and Chen, 1980; Liao and Chen, 1982; Bové et al., 1983), an immediate subculture (1:10–1:100) is commonly made to dilute the infected plant extract. Initial isolations are often done using media of high complexity and richness, as the spiroplasmas must adapt from the very rich environment provided in plant sieve tubes. Later on, spiroplasmas may be "weaned" from such requirements by gradually simplifying the medium (Whitcomb, 1983). Culture establishment can be monitored conveniently by 1) the development of light turbidity in the culture tubes (dense turbidity usually indicates contamination by more prolific species, and because spiroplasmas are both motile and small enough to exhibit Brownian motion, the presence of a pellet at the bottom of the tube also indicates contamination); 2) a color change in an acid-base indicator, indicating the presence of acidic byproducts of metabolism; or 3) an increase in spiroplasma cell counts. The latter are often evaluated using light microscopy and dark-field optics (Tully, 1983) at a magnification of 1000–1250X, at which the helical morphology of spiroplasmas is easily apparent. Helices can also be viewed, but far less clearly, using phase contrast optics at the same magnifications (Bredt, 1983).

Plant pathogenic spiroplasmas also may be isolated from the bodies of their insect vectors, a procedure that, like isolation from plant tissue, may be challenging because of low pathogen titer and the presence of growth inhibitors in the host tissue. Although many species of insect-associated spiroplasmas colonize only the gut lumen of their insect hosts (Markham et al., 1983c), all of the plant pathogenic species invade the body cavity by traversal of the gut epithelium and multiply to relatively high titers in the hemolymph. In some cases the bacterial population reaches higher levels in the hemocoel than in plant phloem, making isolation from insects an attractive alternative (Markham and Townsend, 1979).

As spiroplasma cultures mature, the growth conditions become less optimal; certain nutrients begin to become limiting, the pH of the medium falls, and toxic byproducts may reach concentrations detrimental to the cells. The spiroplasmas divide less frequently under such conditions, and as a result they become longer and have more turns to the helix, but the amplitude of the helical turns decreases as the helices relax. Whereas in young cultures cell division is followed quickly by separation of the daughter cells, older cultures contain many aggregates of spiroplasma cells (called "Medusa's heads" because the helical

cells radiating from a central point resemble the tresses of the famous mythological figure) that presumably result from a failure of daughter cells to separate. As cells age further, cell membrane changes occur, and "blebs" or bulges become visible along the length of the filaments. Finally, the cells lose the filamentous form altogether, assuming a globular shape. In this globular stage the spiroplasmas are generally unrevivable, but at previous stages, the short, tight helical morphology and rapid cell division characteristic of a healthy population can be restored by transferring a small volume into fresh medium (see section Morphology in this Chapter).

Chemically undefined media continue to support the most rapid and prolific growth of many spiroplasmas, but such media are suboptimal for investigations of nutritional requirements of spiroplasmas. In 1982 the first chemically defined spiroplasma medium, CC-494, was reported for some epiphytic species (Chang and Chen, 1982). Although microbial growth rates and maximum titers were reduced, the medium facilitated nutritional analyses. A defined medium for *S. citri* was developed soon after (Lee and Davis, 1983). Lee and Davis (1984) reported that the growth of *S. citri* in LD8 broth reached a titer of over 6×10^9 colony forming units (cfu)/ml at a doubling time of 4 h at 31°C, while *S. kunkelii* reached 2×10^9 cfu/ml, doubling every 11–12 h, at 31°C in LD8A.

Cultivation on Solid Media

All three of the plant pathogenic species of *Spiroplasma* produce colonies on agar-solidified media. Colony sizes vary depending on the titer of the plated suspension, the nutrient content of the medium, and the concentration of the agar. As discussed in the section Morphology, colonies of normally motile spiroplasmas are small, and their edges are indistinct, appearing to be "out of focus," because of the formation of numerous satellite colonies by the swimming cells (Fig. 3).

Colonies of certain nonhelical strains, such as the naturally occurring *S. citri* strain ASP-1, more closely resemble the familiar "fried egg" colonies of zoopathogenic and human mycoplasmas.

When establishing research cultures from a natural source, it is advisable to establish a homogeneous spiroplasma population by subjecting the primary culture to a triple filter-cloning step, using a 0.22-μm filter to remove spiroplasma aggregates and selecting single colonies for propagation (Lee et al., 2001).

Identification and Detection

Many methods are available, and in use, for the detection and identification of phytopathogenic spiroplasmas. The choice of a particular test or tests will depend on the degree of certainty and discrimination required, the specific information desired, and the capabilities of the laboratory in which testing is done.

Dienes' Stain

For rapid assessment of plant samples from field collections, a quick and easy preliminary test for either spiroplasmas or phytoplasmas is to apply Dienes' stain to hand-cut sections of tissue (Deely et al., 1979). Originally developed to aid in visualization of mycoplasma colonies on agar surfaces, the stain directly colors the pathogens so that phloem sieve tubes colonized by spiroplasmas contain irregular patches of deeply stained cells when viewed by light microscopy (Fig. 5). Dienes' stain has some limitations, however. To avoid false positives, it is advisable to include known negative samples in the analysis, and Dienes' staining may be difficult to interpret in older or woody tissues. In addition, Dienes' positive staining reactions have been reported for diseases caused by non-mollicute phloem-resident plant pathogens such as *Serratia marcescens*, causal agent of cucurbit yellow vine

Fig. 5. Horseradish root cross section, stained with Dienes' stain. Large, thick-walled xylem vessels of both healthy (Panel A) and diseased (Panel B) plants retain the blue dye. Blue-stained cell patches (arrow) occur in the phloem region in diseased plants only. Photos: J. Fletcher.
disease, and beet curly top virus in pepper, sugar beet and bean (Bruton et al., 1998).

DAPI

The fluorescent dye DAPI (4′,6-diamidino-2-phenylindole) binds to DNA in a nonspecific manner. Although the binding is nonspecific, labeling host DNA in the nucleus and organelles as well, the dye has been used widely for detection of mollicutes within plant tissues (Seemuller and Kirkpatrick, 1996; Lee et al., 2001).

Electron Microscopy

Because it is tedious and expensive, and because phytopathogenic mollicutes are often distributed irregularly within a plant host and thus may be missed, pathogen visualization at the electron microscope level is used more commonly for the uncultivable phytoplasmas than for spiroplasmas. However, electron microcroscopy (EM) is still useful for spiroplasma detection and has the advantage of showing the wall-less cell morphology characteristic of the mollicutes (Williamson, 1983). Although the long and helical spiroplasmas are often cut in cross- or transverse sections when typical thin sections of tissue are prepared, making spiroplasmas difficult to distinguish from phytoplasmas, "thick" thin sections can be cut that allow visualization of the helical turns of spiroplasmas. Specific considerations for optimal sample collection and preparation, and viewing of spiroplasmas via EM, are available (Waters, 1982; Cole, 1983; Carson and Collier, 1983; Garnier and Bové, 1983; Williamson, 1983; Chen et al., 1989).

Isolation and Cultivation

Detection of phytopathogenic spiroplasmas in infected plants is often accomplished by cultivation in artificial media (see section Cultivation in this Chapter). Because contamination with more aggressive, walled bacteria is a concern, culture media may be supplemented with antibiotics such as tetracycline, which affect protein synthesis rather than cell wall formation, and are generally viewed using light microscopy and dark field optics for high-contrast visualization of typical helices in the media. Isolation can be quantitative if cultivation is done on agar-solidified media, and if samples are adequately replicated and controlled (Kloepper et al., 1982).

Serology

Various strategies in which antibodies, either polyclonal or monoclonal, are used to differenti-ate spiroplasma taxa, have been developed. The growth inhibition test (Taylor-Robinson, 1979), which can discriminate among major spiroplasma serogroups, is performed by placing filter paper discs saturated with specific antiserum onto lawns seeded with spiroplasmas and measuring the resulting zones of growth inhibition. The metabolism inhibition test is similar in concept but carried out in broth medium supplemented with an acid-base indicator dye; the assay is evaluated by a color change. The organism deformation test (Williamson et al., 1978), commonly used to place a spiroplasma into a subgroup, is based on the ability of a specific antibody to alter the spiroplasma's outer membrane surface, resulting in the loss of the helical morphology. Affected cells take on a spherical shape that is readily seen in dark field microscopy. Quantitative relationships among various spiroplasmas may be determined by titration of the antisera. The metabolism inhibition and organism deformation tests may be combined, as reported by Williamson et al. (1979). Anti-spiroplasma antibodies can also be used in simpler, faster assays such as latex agglutination (Fletcher and Slack, 1986) and dot-immunoblotting (Fletcher, 1987).

In the early 1980s, enzyme-linked immunosorbent assay (ELISA) was adapted for the detection and identification of phytopathogenic spiroplasmas. Raju and Nyland (1981a) and Eden-Green (1982) both used the test for detection of the corn stunt spiroplasma in infected plants or extracts therefrom, at concentrations of 10^6 cells/ml or higher. In the latter study, false positives were a problem when leafhoppers (*Dalbulus maidis*) were tested. ELISA also detected up to 10^9 *S. citri* cells per gram of *Catharanthus roseus* (then *Vinca rosea*) tissue and detected the pathogen in samples as small as a single leafhopper (Archer et al., 1982). Lin and Chen (1985) were the first to report the preparation of anti-*S. citri* monoclonal antibodies and their use to discriminate among strains of the spiroplasma. Interestingly, in 1996 the failure of extracts of symptomatic periwinkle plants (collected from *S. citri*-affected citrus groves in the Middle East) to react in ELISA with antiserum against *S. citri* demonstrated the existence of a third species of plant pathogenic spiroplasma that was later designated "*S. phoeniceum*" (Saillard et al., 1996). As with cultivation, ELISA also may be quantitated for use in determining population levels in plant hosts, in different tissues, and over ranges of time (Saillard et al., 1978; Daniels et al., 1982; Fletcher and Eastman, 1984a; Gussie et al., 1995). ELISA test kits, as well as individual antibodies and control samples (positive and negative), for both *S. citri* and *S. kunkelii* are available commercially.

Polyacrylamide Gel Electrophoresis

Before the advent of convenient molecular fingerprinting techniques, polyacrylamide gel electrophoresis (PAGE) patterns in both one and two dimensions were used widely to compare and discriminate among serogroups, subgroups, and strains of plant pathogenic spiroplasmas (Davis and Lee, 1982; Fletcher et al., 1995). In addition, PAGE analyses allowed the clustering of strains into distinct groups, each containing highly related strains. Such analyses later proved to agree well with other methods of identification and classification.

DNA-DNA Hybridization and DNA Probes

As the number of spiroplasma strains increased (most being isolated from arthropod species), the need to more accurately assess their relationships and phylogeny increased. Early comparisons of spiroplasma genome sequences by DNA-DNA homology (Christiansen et al., 1979; Junca et al., 1980; Lee and Davis, 1980) showed that taxonomies and phylogenetic histories suggested by such analyses were in good agreement with the serological data accumulated previously, and taxonomic groupings of spiroplasmas began to be developed. DNA-DNA hybridization has gradually been replaced by the less-difficult amplification and analysis of 16S rDNA sequences.

Polymerase Chain Reaction

Use of the conserved sequences of 16S rRNA have proved to be at least as valuable for the detection of wall-less prokaryotes as for their walled relatives (Deng et al., 1992; Saillard et al., 1996), and even more valuable for the uncultivable phytoplasmas. The method is particularly useful for detection of the mollicutes within their host tissues, plant phloem, or insect vectors, because primer specificity allows the pathogen DNA to be preferentially amplified. Using primers designed from spiralin or from spiroplasma virus DNA sequences, Saillard et al. (1996) developed polymerase chain reaction (PCR) for detection of *S. citri* in periwinkle plants, achieving sensitivity from 100–1000 times greater than that of ELISA. Other common primers are developed from the 16S rRNA genes or from other genes that are highly conserved among taxa. In some cases host components may interfere with the amplification, or spiroplasma titers may be very low in some tissues, giving rise to false negative reactions. Optimization protocols include dilution of the host inhibitors or partial sample purification steps. Altered versions of

PCR also exist. In nested PCR, two primer pairs (one "universal" set and the other either universal or species-specific) are used in tandem to amplify mollicute DNA from very low populations. Immunocapture PCR enriches for spiroplasmas using specific antibodies, giving 10X greater sensitivity in subsequent PCR reactions (Saillard et al., 1996). Bastion and Foster (2001) recently reported identification of a single primer pair that amplified a 276-bp fragment from all spiroplasmas tested except for MQ1 but did not amplify other mollicutes tested. Such primers might be useful as "universal" for spiroplasma detection. On the other hand, primers unique for specific plant pathogenic spiroplasmas also have their place; Barros et al. (2001) recently developed primers based on *S. kunkelii*-unique regions of the sequence of the spiralin gene for detection of the corn stunt spiroplasma but not of *S. citri*.

Genomic Sequence

When the complete genomic sequence is available for the two most commonly occurring phytopathogenic spiroplasmas, *S. citri* and *S. kunkelii* (see the section DNA Sequence in this Chapter), researchers will have the ability to identify any gene or nucleic acid sequence that would differentiate between these two species. Having the genomic sequences also will assist in the selection of genus-specific regions that could be useful in disease diagnosis and pathogen identification. A simple application would be to design PCR primers for amplification of a sequence or sequences previously determined to be discriminatory. Detection of a PCR product may be followed by sequencing of the product to distinguish further among spiroplasmas. See also the section Phylogeny and Taxonomy in this Chapter.

Pathogenicity Tests and Host Range

Because they colonize the phloem, spiroplasmas can be transmitted from plant to plant in some host species by grafting or via the parasitic plant, dodder (*Cuscuta compestris* or *C. subinclusa*; Lee et al., 2001). Madagascar periwinkle, *Catharanthus roseus*, is a commonly used host for the maintenance and propagation of plant pathogenic mollicutes, including spiroplasmas, because it is readily available, easy to grow, readily grafted, and susceptible to most of the mollicute pathogens. Furthermore, the symptoms produced on periwinkle vary with the pathogen species, significantly in some cases and subtly in others; seasoned researchers are able to distinguish such symptoms.

Preservation

Storage of spiroplasmas may be more challenging than for other bacteria because of the absence of a cell wall. Mid- to late-log phase cultures quick-frozen in small aliquots (100–500 μl) of liquid growth medium at ultra-low temperature (–70° to –80°) or in liquid nitrogen generally remain viable for a number of years; freezing at warmer temperatures may be successful for shorter periods. Lyophilization (freeze-drying) in growth medium is preferred for extended storage (Leach, 1983). A quick and easy method for transfer or mailing of spiroplasmas is to place drops of log-phase cultures on small discs of filter paper and dry them in a desiccator without vacuum; such cultures can be revived after 6 wk at room temperature and 3 months at 4°C (Liao and Chen, 1982). Because spiroplasmas cannot be mechanically transmitted to plants, a disadvantage of this method of storage is that plant inoculations require insect vector acquisition, either by feeding the insects on spiroplasma suspensions or by needle inoculation into the hemocoel of the insect vectors. Because of the high natural mutation rate of spiroplasmas in culture (see section Genetics in this Chapter), storage of the early passage cultures of plant or insect isolates is very important. Aliquots of both the original (uncloned) isolate as well as of several clones of the triply cloned population should be stored.

For convenience in plant experiments, plant pathogenic spiroplasmas are often maintained in plant hosts or insects or both. Long lived plant species that are easy to grow and amenable to grafting, such as Madagascar periwinkle (*Catharanthus roseus*), are usually chosen to circumvent the labor-intensive requirement for insect inoculations. However, long-term lack of exposure of the spiroplasmas to their insect vectors (and the accompanying lack of selection pressure from that part of their normal lifecycle) may lead to loss of the ability to be insect transmitted. For example, a strain of *S. citri* BR3-3X (maintained for 10 years in periwinkle by successive grafting) was found to be nontransmissible by the beet leafhopper, *C. tenellus* (Wayadande and Fletcher, 1995). Several researchers have noted also that spiroplasma strains passaged by grafting may lose virulence for the plant host over time. After several years of in planta graft maintenance, *S. citri* strains once able to kill a periwinkle host plant in 1–2 weeks produce only a mild mottling, and infected host plants may survive for months.

Physiology and Metabolism

The physiology of members of the Class Mollicutes has been studied primarily in the genus *Mycoplasma*; for excellent reviews, see Pollack (1992), Finch and Mitchell (1992), Fischer et al. (1992), McElhaney (1992), and Pollack et al. (1997). The first spiroplasmas to be discovered, plant pathogens, were designated "fastidious" prokaryotes because of the difficulty encountered in their cultivation and the complex mixtures of compounds ultimately required for their in vitro growth (see the section Cultivation in this Chapter). Interestingly, phytoplasmas, the other plant pathogens of the Class Mollicutes, remain uncultivable despite focused efforts to identify suitable media. The resistance of these plant pathogenic mollicutes to cultivation probably reflects the loss of metabolic functions resulting from adaptation to a parasitic lifestyle in their plant hosts and insect vectors.

Intermediary Metabolism (Sugars and Energy)

RESPIRATORY PATHWAYS. The spiroplasmas are unusual in their energy-generating mechanisms. Early investigators (Hollander et al., 1977) suggested that respiratory chains were absent and the microbes' inability to reduce redox indicators support that conclusion (Pollack et al., 1996). Unlike other spiroplasmas, however, the phytopathogenic spiroplasmas do have oxidoreduction sites, but they occur exclusively at the blunt end of the organism (Garnier et al., 1984). Organisms having respiratory chains use the generated energy to synthesize ATP via a proton-ATPase. A proton-ATPase has been identified in spiroplasma by serology (Rottem et al., 1987), but since the microbes lack the other components of respiratory metabolism this enzyme likely functions in pH stasis.

Lacking oxidative metabolism, phytopathogenic spiroplasmas use the nonoxidative breakdown of sugars to generate energy. The effectiveness of the pathway is shown by the fact that the adenylate energy-charge of tested mollicutes is similar to that of *S. citri* and other bacteria (Beaman and Pollack, 1983). Genes for each of the enzymes of the glycolytic pathway can be recognized in the genome sequence of *S. kunkelii* (Table 2). Although in most organisms the enzyme lactate dehydrogenase is very specific for its substrate, in some mycoplasmas it also functions as a malate dehydrogenase. In *S. melliferum*, a close relative of *S. citri,* there are two separate enzymes (Cordwell et al., 1997). Curiously, no evidence of a gene for a separate malate dehydrogenase is found in the *S. kunkelii*

Table 2. Distribution of functions of genes identifiable in the *S. kunkelii* genome project.

Class	Number	Percent
?	1	0.1
Biosynthesis of cofactors, prosthetic groups, and carriers	6	0.5
Cell envelope	26	2.3
Cell/organism defense	2	0.2
Cellular processes	20	1.7
Central intermediary metabolism	11	1.0
DNA metabolism	40	3.5
Energy metabolism	21	1.8
Fatty acid and phospholipid metabolism	4	0.3
Hypothetical proteins	96	8.3
Protein fate	6	0.5
Protein synthesis	60	5.2
Purines, pyrimidines, nucleosides, and nucleotides	16	1.4
Regulatory functions	1	0.1
Transcription	8	0.7
Transport and binding proteins	38	3.3
Unknown	678	58.8
Viral	120	10.4
Total	1154	100.0

genome sequences (Table 2). The ability to oxidoreductively exchange malate and oxaloacetate undoubtedly plays a role in the maintenance of oxidized to reduced free nicotinamide-adenine dinucleotide (NAD+/NADH) ratios.

SUGAR METABOLISM. The sugars available to phytopathogenic spiroplasmas are different in their two eukaryotic hosts. In plants, where spiroplasmas colonize phloem elements, they are exposed to relatively high concentrations of sucrose and to lower concentrations of its component monosaccharides, glucose and fructose. In contrast, the disaccharide trehalose is the major sugar in leafhopper hemolymph (Andre et al., 2003), but this sugar is composed only of glucose. Thus, one can expect that the spiroplasmas have a versatile sugar metabolism that can adapt to two substantially different environments, one glucose-rich and the other a balanced glucose-fructose environment.

The ability of the spiroplasmas to grow using trehalose apparently stems from an ability to import and hydrolyze the sugar. The genomes of *S. citri* (W. Maccheroni and J. Renaudin, cited in Bové et al., 2003) and *S. kunkelii* contain a three-cistron operon (U. Melcher, unpublished observations; see also http://www.genome.ou.edu/spiro.html {Spiroplasma kunkelii Strain CR2-3x Genome Sequencing Web site}). The second cistron encodes a trehalose permease component, IIBC, of a phosphotransferase system, while the third encodes the amylase needed to hydrolyze the disaccharide. The other component of treha-

lose permease II contains a IIA domain like those that, in most other sugar permeases, are covalently attached to IIBC domains. The IIA-domain polypeptide is synthesized from a separate gene (Andre et al., 2003). It also serves as the IIA component of a glucose permease, whose IIBC component is encoded by still another gene. The first cistron of the trehalose operon, *treR*, putatively encodes a positive regulator of the trehalose operon.

In contrast, in plants, the disaccharide is not taken up by the spiroplasma and subsequently hydrolyzed. Indeed, the spiroplasmas are unable to grow on sucrose as a carbon source. However, they are able to take up and metabolize glucose and fructose by separate pathways. Glucose uptake is mediated by a glucose permease, whereas fructose is taken up and phosphorylated by a fructose permease, the product of the *fruA* gene. The fructose-1-phosphate is further phosphorylated to fructose-1,6-bisphosphate by 1-phosphofructokinase, the product of the *fruK* gene. The phosphofructokinase itself is probably not strongly regulated by phosphoenolpyruvate as in many other bacteria, since it has an aspartic acid at position 187 (Auzat et al., 1994); only tightly regulated enzymes have a glutamic acid at this position. The *fruA* and *fruK* genes form an operon analogous to the trehalose operon, with a fructose regulatory cistron, *fruR,* located as first cistron of the *fru* operon. The *fru* operon is regulated by fructose through FruR (Gaurivaud et al., 2001), which likely is an activator of transcription.

Inactivation of the *S. citri* fructose utilization gene cluster (Gaurivaud et al., 2000) by insertion mutagenesis or selection for xylitol resistance (Gaurivaud et al., 2000) gave rise to spiroplasmas that produced delayed and milder symptoms on periwinkle plants (Gaurivaud et al., 2000). Complementation of mutants with fructose operon genes restored both fructose utilization and wildtype pathogenicity. Fructose in culture stimulates transcription of the operon only when an active *fruR* is present, supporting the identification of FruR as a positive transcription regulator. Fructose utilization may inhibit phloem loading of sucrose in the source leaves. The resulting deficiency of sugar in sink leaves and excess in the source leaves may lead to pathogenic effects (Bové and Garnier, 2002; Bové et al., 2003; see also the section Virulence Mechanisms in this Chapter). Still unclear is whether spiroplasmas are restricted to scavenging the low concentrations of glucose and fructose available in phloem or whether they actively alter plant metabolism to provide the bacteria greater fluxes of sugars. The overall picture to emerge is that appropriate positive regulation of the host-specific pathways ensures that only the

pathway appropriate for the host of residence is active at any one time.

Regulation

Regulation via *fruR* and, putatively, via *treR* represent two of but a handful of documented or suspected regulatory mechanisms in phytopathogenic spiroplasmas. *Spiroplasma citri* does not contain calmodulin, a protein that could modulate calcium-dependent regulation (Barth et al., 1991). Regulation by protein phosphorylation is a possibility since a protein of 57 kDa from *S. melliferum* is phosphorylated in vivo (Platt et al., 1990). *Spiroplasma citri* can obtain energy from arginine (Townsend, 1976), and both *S. citri* and *S. kunkelii* contain an aminopeptidase active on arginine substrates (Stevens et al., 1984). Growth of these spiroplasmas in the presence of arginine reduced the level of the enzyme accumulated, suggesting a feedback regulation. The pathway of ATP-generating arginine catabolism in mollicutes requires the enzymes arginine deiminase, ornithine carbamoyltransferase, and carbamate kinase, for which encoding genes were detected in the *S. kunkelii* genome (U. Melcher, unpublished data).

Lipids and Membranes

The basic outlines of spiroplasma lipid metabolism were sketched by feeding studies and compositional analyses (Freeman et al., 1976). Phytopathogenic spiroplasmas cannot synthesize fatty acids and thus require exogenous fatty acids for growth (Pollock, 1987). Spiroplasmas take up phospholipids directly and incorporate them into membranes with little or no modification (Rottem et al., 1986). Membranes contain sphingomyelin (Razin et al., 1973; Davis et al., 1985) and cholesterol and are rich in phosphatidylglycerol (Mudd et al., 1977), of which spiroplasmas can synthesize only the latter. The *S. kunkelii* genome contains genes that likely produce an acyl carrier protein (ACP), an ACP phosphodiesterase, a CDP-diacylglycerol kinase, and glycerol-3-phosphate dehydrogenase, enzymes having key roles in phospholipid metabolism. *Spiroplasma citri* and other spiroplasmas, in contrast to mycoplasmas, have neither lipopolysaccharide-like (Smith et al., 1976) nor lipoglycan (Smith, 1984) molecules. The membranes of the closely related phytopathogens *S. citri* and *S. kunkelii* are likely to be very similar in composition and function, but although their compositions were judged identical in one study (Patel et al., 1978), they were found to have minor differences in another (Mudd et al., 1979).

Proteins

GENERAL. The protein content of spiroplasmas can be fractionated by electrophoresis and characterized (Cordwell et al., 1995; Cordwell et al., 1997). Some spiroplasma proteins separated by two-dimensional (2-D) gel electrophoresis (Wroblewski, 1981) lacked extensive disulfide crosslinkages. One of these, D16, is an 89-kDa protein (probably identical to spiroplasma adhesion-related protein (SARP)1, an adherence-associated protein of *S. citri*; Berg et al., 2001) that shows amino acid sequence similarity to an adhesin of *M. agalactiae* (Fleury et al., 2002; see the section Molecular Biology in this Chapter). Even 1-D gel electrophoresis is useful; protein profiles of *S. citri* lines differing in pathogenicity and transmissibility characteristics showed phenotype-related pattern differences including the presence of a 144–146 kDa band in transmissible lines and its absence in nontransmissible ones (Fletcher et al., 1996).

MEMBRANE PROTEINS. The membrane proteins of phytopathogenic spiroplasmas may be isolated by several means. For example, those of *S. citri* can be isolated by extraction with sodium desoxycholate (Wroblewski, 1975), sarkosyl (Wroblewski et al., 1978), or by alternate cycles of detergent (such as Triton-X 114) and aqueous extraction (Fletcher and Wijetunga, 1981).

Proteins having surface domains on the phytopathogen *S. citri* BR3 were identified by their sensitivity to proteases and antibodies and by ^{125}I-labeling studies (Fletcher et al., 1989). Most surface-exposed proteins of *S. citri* are resistant to proteinase K (Yu et al., 1997; Yu et al., 2000), but the adherence-associated protein SARP1 is readily cleaved, leaving behind a 48-kDa remnant. Cleavage correlated with loss of the spiroplasmas cells' ability to bind to leafhopper cells in culture. On the other hand, others (Butler et al., 1991) have found general susceptibility of spiroplasmas membrane proteins to proteinase K and identified a proteinase resistant protein, p40-pr, of unknown function.

As with other bacteria, spiroplasma membranes contain a number of enzymes (Kahane et al., 1977; Mudd et al., 1977). Using zymograms and zymoblots to identify enzyme functions in *S. citri,* Wagih and Fletcher demonstrated that *S. citri* possessed esterase, ribonuclease and tyrosinase activities but lacked several enzymes common to most prokaryotes (Wagih and Fletcher, 1988; Wagih and Fletcher, 1993). Several important enzymes were demonstrated to be present directly in osmotic lysates of spiroplasmas, including *S. citri* (Chen and Chang, 1994).

SPIRALIN. Spiralins (Bové et al., 1993) are abundant, acylated (Wroblewski et al., 1989)

proteins of about 29 kDa covering the spiroplasma plasma membrane like a carpet (Castano et al., 2002). Minor amounts of a larger spiralin form are present within *S. citri* cytoplasm, suggesting that a prespiralin is processed to remove a prepeptide (Mouches et al., 1984). When synthesized in *E. coli* (Mouches et al., 1985) from a transgene (Bové et al., 1984), spiralin was found in the cytoplasm and in both the inner and outer membranes, in three molecular weight forms (Blanchard et al., 1987). Spiralins are molecularly heterogeneous because of posttranslational modifications (Foissac et al., 1996), possibly variable acylation of the N-terminus and the *S*-glycerylcysteine (Wroblewski et al., 1987; Le Henaff and Fontenelle, 2000; Le Henaff and Fontenelle, 2002).

Probably as a result of the lipid moieties attached, spiralin is an intrinsic membrane protein (Wroblewski, 1979), resistant to agents removing peripheral proteins and extractable by detergents (Blanchard et al., 1985; Plusquellec et al., 1989). Of interest to spiralin's relationship to membranes is a 20-residue, putatively amphipathic peptide (Bondon et al., 1995). Circular dichroism studies show such spiralin peptides to have unordered structure in aqueous solution but to form alpha helices in lipid micelles (Brenner et al., 1995).

Spiralin sequences, deduced from their gene sequences from *S. melliferum* (Chevalier et al., 1990), *S. citri* (Chevalier et al., 1990), *S. phoeniceum* and *S. kunkelii* (Foissac et al., 1997), reveal evidence of positive selection for substitutions that alter the protein's amino acid sequence (Foissac et al., 1997). This observation, and the prevalence of the protein on the cell surface, support the hypothesis of a major role for spiralin in host interactions. This hypothesis was supported when disruption of the spiralin gene by homologous recombination using an *oriC*-derived plasmid resulted in a considerable decrease in leafhopper transmissibility despite no decrease in pathogenicity (Duret et al., 2003), indicating that the spiralin-relevant host interaction is with the leafhopper, rather than the plant host.

Nucleic Acids

The small cell size of spiroplasmas compared to other bacteria is accompanied by a small genome that lacks a considerable number of common bacterial genes (see the section Genetics: General Characteristics in this Chapter). Nevertheless, *S. kunkelii* exhibits a small repertoire of easily recognized genes for enzymes of purine and pyrimidine metabolism (U. Melcher, unpublished observations; Table 2): cytidine deaminase, uridine and thymidine kinases, cytidylate kinase, purine-nucleoside and thymidine phos-

phorylases, thymidylate synthase, and GMP reductase.

Genes involved in DNA replication and repair have been studied in both *S. citri* and *S. kunkelii*. The former spiroplasma contains at least two DNA polymerases (Charron et al., 1979) and probably three (Charron et al., 1982), as in *A. laidlawii* but not as in *M. mycoides*, which has but a single enzyme (Maurel et al., 1989). The *S. kunkelii* genome sequence shows clear evidence of the presence of genes for DNA polymerase I and III homologs but not for a DNA polymerase II. In addition, signatures of genes for other enzymes involved in DNA synthesis and function are present: DNA topoisomerases I, II and IV, DNA primase, DNA ligase, DNA helicase, and single-stranded DNA binding protein. Several DNA repair enzyme genes can also be recognized, those encoding: DNA photolyase, excinuclease ABC, endonuclease IV and formamidopyrimidine- and uracil-DNA glycosylases. Earlier studies demonstrated that *S. citri* is more sensitive to ultraviolet (UV) radiation than is *Escherichia coli*, but the UV sensitivity curves do indicate the presence of some DNA repair capabilities (Labarere and Barroso, 1984). No evidence for a dark repair system was obtained, but the presence of an SOS type repair system was suggested (Labarere and Barroso, 1989). The *recA* gene of *S. citri* is truncated and probably not functional; that of *S. melliferum* contains a stop codon in its middle (Marais et al., 1996), but the gene may be functional, as the stop codon is likely read-through (Melcher et al., 1999b).

Genetics

The general characteristics of spiroplasma genomes have been known for some time, as have a few nucleotide sequences, but much more has been learned in recent years. Sequence information has burgeoned and genetic mechanisms are being characterized. Extrachromosomal elements, consisting of plasmids and phage replicative forms (RF), are being better delineated. Methods for genetic characterization by gene introduction and gene inactivation have been developed and are yielding significant insights.

General Characteristics

G+C CONTENT AND METHYLATION. The plant pathogenic spiroplasmas have G+C contents of 25–27 mol%, as do several related spiroplasmas, levels even lower than the 29–32% found in other spiroplasmas (Bové et al., 1982). The sizes of spiroplasma genomes vary widely (Carle et al., 1995); those of the phytopathogenic

spiroplasmas are 1.5–2.2 Mbp but can change rapidly by mutation within even a few generations (Ye et al., 1996). Consistent with the small genome size, spiroplasmas, like several other mollicutes, contain a single rDNA set (Razin et al., 1984a; Razin et al., 1984b); mollicutes in general have a lower number of rRNA genes than their larger genomed relatives (Amikam et al., 1984). The states of DNA methylation are highly divergent among the spiroplasmas (Nur et al., 1985), and both cytosine and adenine can be targets of methylation. Although methylcytosine occurs only in CA and CT sequences in *S. apis*, in *S. floricola* it is found in all CN dinucleotides. The methylation occurs by modification methyllases, which protect the organism from their own restriction endonucleases. Spiroplasmas encode multiple restriction endonucleases. For example, *Sci*N1, which has been purified and characterized, cleaves at CGCG sequences and is thought to play a role in protecting *S. citri* against phage infection (Stephens, 1982).

REPETITIVE ELEMENTS. Short repetitive sequences are present in the chromosomes of *S. citri*, *S. kunkelii* and *S. phoeniceum* strains, but not in those of nine other spiroplasma strains examined (Nur et al., 1987). Similar repeats found in a cloned fragment of the abundant (Razin et al., 1987) plasmid pRA1 from *S. citri* R8A2 were derived from an SpV3 phage (Ranhand et al., 1987). On long passage in culture, the pRA1 sequences become integrated in the chromosome (Razin et al., 1987).

GENE ORDER. Comparison of a restriction map of *S. citri* R8AH2.HP, published in 1992 (Ye et al., 1992), with maps generated for *S. melliferum* (Ye et al., 1994) and other spiroplasmas revealed considerable heterogeneity among group I spiroplasmas, even within the *S. citri* species (Ye et al., 1995a; Ye et al., 1996). However, the finding that synteny between *S. citri* and *S. melliferum* is violated by only a single inversion strongly supports the recent evolutionary divergence of these two genera (see the section Phylogeny and Taxonomy in this Chapter).

Genetic Code

Spiroplasmas have an unusual nucleotide codon usage feature. They contain two tRNA$_{trp}$, one recognizing UGG and the other recognizing UGA, as first reported for *S. citri* by Citti et al. (1992). This observation and the finding that several protein coding genes contained in-frame UGA codons suggested that in spiroplasmas UGA is not a stop codon but a tryptophan (trp) codon. The fact that mutation of UGG to UGA did not stop expression of the gene in which the mutated UGG trp codon was located (Stamburski et al., 1992) provided further evidence that

UGA coded for trp in *S. citri*. The same codon usage is found in other spiroplasmas as well.

Protein Processing

Proteins synthesized by the translational machinery may be processed by a typical signal peptidase. That spiroplasmas have a signal peptidase gene was first inferred because the peptidase inhibitor globomycin prevented processing of spiralin, the major protein of the external surface (Beven et al., 1996). More recently, several other spiroplasma proteins, for example SARP1 (Berg et al., 2001), have been characterized as having a mature N-terminal amino acid sequence corresponding to expectation from signal peptidase processing.

DNA Sequence

Until recent technology permitted the sequencing of entire bacterial genomes, gene sequence analysis focused on particular genes of regions of interest. Early studies of *S. melliferum* included the characterization (Rogers et al., 1984) and sequencing (Rogers et al., 1986) of a tRNA gene cluster (Rogers et al., 1987). A genome section containing the *rpoB* gene (Laigret et al., 1996), which codes for the β-subunit of RNA polymerase, also contains an *hsd* gene, which is possibly involved in type I restriction and modification systems, and phage sequences. The origin of replication, *oriC*, and the adjacent *dnaA* gene, responsible for the initiation of DNA replication, also were identified and sequenced (Ye et al., 1994). Gene organization in *S. citri* resembles that in a *Lactobacillus*, at least in the vicinity of the phosphofructokinase gene (Branny et al., 1993). The region also encodes the *rpsB* product (a ribosomal protein), elongation factor Ts (a component of the protein biosynthesis elongation cycle), spiralin, pyruvate kinase (Chevalier et al., 1990), and three other proteins (Le Dantec et al., 1998). Near the 3' end of the *rpsB* gene is a 20-bp inverted repeat that serves as a binding site for ribosomal protein L29, suggesting that the latter serves a regulatory role as well as a role in ribosomal structure and activity (Le Dantec et al., 1998). Numerous sequences have been found to be polymorphic among *S. citri* strains (Bové et al., 1990), and mechanisms to account for such polymorphisms have been proposed (Melcher et al., 1999b).

The first published report of investigation of *S. kunkelii* genome sequences was that of a survey sequence pilot project (Bai and Hogenhout, 2002a). Genome sequencing projects were initiated for *S. kunkelii* CR-2 in the United States (Zhao et al., 2003; Davis et al., 2004), and for *S. citri* GII3 in France (Gasparich, 2002; Foissac,

2004). Unannotated *S. kunkelii* sequences have been publicly available (http://www.genome.ou.edu/spiro.html {Spiroplasma kunkelii Strain CR2-3x Genome Sequencing Web site}) and the project is nearing completion with the assembly of the 1.55-Mbp genome. Annotations and analyses of partially assembled sequences have been published and include the characterization of an 85-kbp segment containing ribosomal protein genes (Zhao et al., 2003), ATP-binding cassette (ABC) systems (Zhao et al., 2004), and a cell division gene cluster (Zhao et al., 2004).

Only a few *S. citri* GII3 sequences have yet been made public, yielding information on glucose and trehalose permease operons (Andre et al., 2003). A search strategy identified four genes present in two phytopathogenic phytoplasmas and *S. kunkelii* but absent from selected *Mycoplasma* genomes (Bai et al., 2004b). These genes, encoding a polynucleotide phosphorylase, a CMP binding protein, and two less clearly identifiable proteins, may thus be involved in plant infection or insect transmission to plants (see the section Virulence Mechanisms in this Chapter).

Genetic Mechanisms

ULTRAVIOLET LIGHT. Spiroplasmas, particularly those in young cultures (Labarere and Barroso, 1989), are sensitive to UV radiation (Labarere and Barroso, 1984), and arsenic acid- and xylitol-resistant mutants of *S. citri* were recovered after UV treatment. Mutants are able to recombine when incubated for 90 min, suggesting that genetic exchange may be taking place.

GENE EXCHANGE. Spiroplasmas may exchange genes by a DNAse resistant mechanism (Barroso and Labarere, 1988). A recent electron microscopy study of *S. kunkelii* (Ammar et al., 2004) showed structures thought to be pili that could function in conjugation and DNA exchange (see section Morphology in this Chapter). Homologous recombination is thought infrequent in phytopathogenic spiroplasmas because of the absence of a complete copy of *recA* (Marais et al., 1996), a gene that, in most bacteria, functions in homologous DNA recombination and DNA damage repair. Nevertheless, recombination has been observed to occur in *S. citri* GII3 between an introduced replicating plasmid DNA and homologous sequences in the chromosome (Renaudin et al., 1995). Integration can occur at a targeted gene but will also occur in the *oriC* region owing to the presence of *oriC* sequences in the plasmid. Consistent with active recombination systems, integrated SpV1 phage sequences have been implicated in a variety of genome shuffling events (Melcher et al., 1999b). For example, *S. citri* BR3-3X has sustained a large inversion with accompanying small deletions (Ye et al., 1995b) and multiple insertions (Ye et al., 1996) during laboratory propagation.

INSERTIONAL MUTAGENESIS. Often employed to identify genes, insertional mutagenesis, may be done using intact transposons such as Tn*4001* or transposomes. After Tn*4001* mutagenesis of *S. citri* GII3, colony morphology screening resulted in the identification of a motility deficient spiroplasma (Foissac et al., 1997). The inactivated gene, designated "*scm1*," could be complemented with the wildtype gene (Jacob et al., 1997). Tn*4001* insertion in the *S. citri fruR* gene, which is located in the fructose operon, abolished the ability of *S. citri* to utilize fructose and also to produce disease (Gaurivaud et al., 2000; see the section Virulence Mechanisms in this Chapter). Tn*4001* insertion in an *S. citri* gene encoding a lipoprotein that is a solute-binding ABC transporter reduced transmission to plants by *C. hematoceps* (Boutareaud et al., 2004; see the section Insect Transmission in this Chapter). Transposomes, pieces of DNA with transposon ends to which transposase molecules are covalently attached, have been used to generate random, stable insertions in the genome of *S. citri* BR3-3X (Mutaqin et al., 2003; Mutaqin et al., 2004).

Extrachromosomal DNAs

Extrachromosomal DNAs in spiroplasmas (Renaudin, 2002) include plasmids and the replicative forms of bacteriophage genomes. Though found in many groups of spiroplasmas, including the phytopathogenic species in group I, extrachromosomal elements are not universal in spiroplasmas (Gasparich et al., 1993). Some species, for example *S. floricola*, have no detectable extrachromosomal elements.

PLASMIDS. Extrachromosomal closed circular DNAs exist in a variety of spiroplasmas in high abundance, up to 12% of the DNA mass (Ranhand et al., 1980). Characterized by electron microscopy, these DNA molecules were thought not to represent viral DNA forms. Plasmids (Harasawa and Barile, 1983) from a number of *S. citri* strains have been characterized (Bové et al., 1984), and their conservation and distribution among species are quite variable. For example, the distribution of one plasmid from *S. citri* strain ASP-1 was not universal among *S. citri* strains and spiroplasma species (Barber et al., 1983), and sequences similar to those of plasmid pM41 of *S. citri* (Mouches et al., 1984) have been found in many other, but not all, *S. citri* strains as well as in other spiroplasma species (Mouches and Bové, 1983a). Like those from other bacteria, spiroplasma plasmids may carry genes for antibiotic resistance. Transfer of

the erythromycin resistance of *S. citri* strain M4 Er-1 to *S. citri* R8A2 (by alkali cation plus polyethylene glycol treatment) was associated with transfer of a plasmid, pM42 (Salvado et al., 1989). Plasmids pBJS of *S. citri* BR3-3X (Joshi et al., 2004) and pSKU46 of *S. kunkelii* CR2-3X (Davis et al., 2004), each 13–14 kbp in size, contain genes for plasmid transfer, including *traE*, *mob* and *soj*. A pair of origins of transfer, *oriT*, have been identified in pSKU46, resulting in assignment of the plasmid to the IncP incompatibility group (Davis et al., 2004). Two of four *S. kunkelii* CR2-3X *traE* genes also are located on extrachromosomal DNA (Bai et al., 2004a). The *traE* gene of pBJS appears to be located at the end of a three-cistron operon, the other cistrons of which encode the adherence-associated membrane protein SARP1 and an unidentified seven transmembrane helix protein (Joshi et al., 2004). The pBJS plasmid is not present in all *S. citri* strains, but some strains lacking it have related plasmids, identified by DNA hybridization, that lack the *arp1* coding sequences. About three quarters of spiroplasma extrachromosomal elements are thought to contain SpV1 or SpV3 sequences (Gasparich et al., 1993) and may thus contribute to instability of these plasmids as cloning vectors. Interestingly, preliminary reports indicate that *S. citri* strain GII3 has six plasmid DNAs, of which five contain one or more *arp1* homologues, for a total of eight such genes (Foissac et al., 2004). Apparently, strains of phytopathogenic spiroplasmas differ widely in their contents of these plasmids.

VIRUSES. Soon after their discovery, phytopathogenic spiroplasmas were shown to be infected with phages (Cole et al., 1973). The diversity of mollicute-infecting phages (Maniloff et al., 1977; Jansson et al., 1982; Maniloff, 1988) suggests that spiroplasmas are unusual among the class in being frequent phage hosts. Phytopathogenic spiroplasmas host at least four kinds of phages, designated SpV1 (Renaudin and Bové, 1994), SpV2 (Cole et al., 1973), SpV3 (Cole et al., 1977), and SpV4 (Renaudin and Bové, 1994). Not all non-phytopathogenic spiroplasma species harbor phages, however (Chastel et al., 1987). Indeed virus-related sequences, as determined by Southern blotting, are limited to group I spiroplasmas.

SpV1-like phages have been observed in many spiroplasmas (Liss and Cole, 1982). Each spiroplasma strain is resistant to the SpV1 phage it harbors but is susceptible to others (Liss and Cole, 1982). These phages are plectroviruses in the family Inoviridae and have properties associated with the family: they are rod-shaped, packaged by budding from the cell surface, and have single-stranded DNA in the particles with an intracellular double-stranded DNA replica-

tive form (RF). The first SpV1 phage genome to be completely sequenced, SpV1-R8A2 B (Renaudin et al., 1990), encodes an IS30 family insertion sequence (Dong et al., 1992). SpV1-C74 (Renaudin, 1996), in contrast, encodes a transposase characteristic of the IS3 family (Melcher et al., 1999b). Both circular phage genomes have inverted repeat sequences characteristic of their insertion sequence family. These repeats are adjacent but separated by a spacer whose length is also a characteristic of the family to which the elements belong. Thus, the phage genomes resemble circular DNA IS element transposition intermediates. The SpV1-like phage SVTS2, isolated from the group I spiroplasma *S. melliferum,* also infects *S. citri.* Traces of its genome in *S. kunkelii* suggest that it infects this species also. Its complement of genes resembles those of the *S. citri* phages, except for the transposases, which are replaced in SVTS2 by a replication protein cistron (Sha et al., 2000).

SpV2 viruses, tailed phages in the Siphoviridae, have been observed by electron microscopy but neither propagated nor further characterized (Cole et al., 1973). An *S. citri* membrane protein, P58 (Ye et al., 1997), identified because of its deletion during a rearrangement that led to a leafhopper nontransmissible strain (Ye at al., 1996), has convincing similarity in amino acid sequence to terminases encoded by phages of the Siphoviridae. Southern hybridization revealed multiple copies in almost all strains of *S. citri* and *S. kunkelii* tested. For example, at least half a dozen full or partial diverged copies of the P58 gene occur in the *S. kunkelii* CR2-3X genome (J. Comer et al., unpublished observations). The copies appear to have resulted from recombination between two parental sequences. Homologues of the P58 gene also are present in the *Ureaplasma parvum* genome, where they and several flanking genes that are also homologous to genes in *S. citri* and *S. kunkelii* occur in the same order as they do in the latter two species (J. Comer et al., unpublished observations). On the other hand, no P58 copies were detected in other *Spiroplasma* species, mycoplasmas, or phytoplasmas. The observations are consistent with these genes being remnants of infection of plant phytopathogenic spiroplasma by at least two SpV2-like phages distantly related to a ureaplasma phage. Alternatively, the genes could be the result of an ancient infection of an early mollicute ancestor, followed by loss of the genes from all but a few of the derived lineages.

SpV3 phages are poyhedra with short tails (Cole et al., 1977). They have been found in *S. citri*, the suckling mouse cataract agent *S. mirum* (Cole et al., 1977), and the *Drosophila* sex ratio organism, *S. poulsonii* (Cohen et al., 1987). An incomplete form of the genome of ai, an SpV3

phage, was found in the genomes of all strains of *S. citri* examined (Dickinson and Townsend, 1984). The absence of sequence information for these phages precludes identification of their prophages in the *S. kunkelii* CR2-3X sequence.

Virions of SpV4, a member of the Microviridae (Renaudin et al., 1984), resemble phiX174 particles except that they have 20 protrusions extending from the icosahedron, whereas phiX174 virions have no protrusions (Chipman et al., 1998). The genome sequence of SpV4 was the first complete mollicute virus sequence determined (Renaudin et al., 1987a; Renaudin et al., 1987b) and analyzed (Renaudin et al., 1987c). The identification of transcription start and stop sites on SpV4 DNA led to the identification of probable promoter and terminator sequences active in phytopathogenic spiroplasmas (Stamburski et al., 1990). That *S. citri* could be transformed with exogenous DNA was first demonstrated with SpV4 (Bové et al., 1984).

Viral nucleic acid sequences are frequently found integrated in the spiroplasma chromosome (Renaudin et al., 1990). Probably through repeated cycles of phage infection, integration and divergence, the genomes of *S. kunkelii* and *S. citri* have accumulated many degenerated copies of SpV1-like phages. Representatives of each SpV1-R8A2 B, SpV1-C74 and SVTS2 phages are present. Terminal sequences of phage genomes integrated in the *S. kunkelii* genome actually suggest that two distinct phages related to each SpV1-R8A2 B and SpV1-C74 have participated (U. Melcher and J. Fletcher, unpublished observation). A remarkably high percentage (10–20%), of the genomes of phytopathogenic spiroplasmas consists of phage-derived sequences. Early reports that plasmid sequences are found, by Southern blotting, in chromosomal DNA of *S. citri* and other spiroplasma species (Mouches et al., 1984) may indicate that these extrachromosomal DNAs were RFs of phages. Independent recombination events eliminating the degenerated viral sequences prevent the genome from indeterminately expanding (Melcher and Fletcher, 1999a). However, genome sizes can expand rapidly during laboratory propagation (Ye et al., 1996), presumably because of continuing integration events.

Viral integrations may be neutral or beneficial to the spiroplasmas. For example, integration events may lead to gene inactivation (Melcher et al., 1999b), and subsequent recombination events can result in inversions of large parts of the chromosome, both during speciation and during laboratory propagation (Ye et al., 1996). Other integration events provide host gene regulatory signals. For example, transcription termination in the fructose operon of *S. citri* has been inferred to occur at a terminator supplied by a phage sequence at the end of the *fruK* gene (Gaurivaud et al., 2000). In the case of spiroplasma viruses, integration may confer immunity to subsequent infection by that virus or a closely related one. Resistance of natural mutants of *S. citri* to infection with SVTS2 was inferred to reflect classical phage immunity (Sha et al., 1995) since electroporation of the viral RF into cells did not initiate an infection, and the mutant strains contained integrated viral sequences not present in the parent. On the other hand, that *S. citri* strain R8A2 is susceptible to phages SpV1-R8A2B and SpV1-C74 (Renaudin, 2002), even though its genome contains phage-related sequences, can be attributed to evolutionary divergence of viral sequences after integration, leading to inactivation of the immunity factor.

Fig. 6. Left ends of two groups (A and B) of SpV1-C74-like sequences in the *S. kunkelii* genome. Red font shows the conserved end sequences. Black font distinguishes point mutations in the ends and the nonrelated flanking sequences. Two distinct groups were also found for SpV1-R8A2 B-like sequences.

Molecular Genetic Methods

TRANSFORMATION AND TRANSFECTION. That *S. citri* could be transformed with exogenous DNA was first demonstrated with the DNA spiroplasma phage SpV4 (Bové et al., 1984), but the use of plasmids as vectors has generally been more successful than the use of viruses. For example, when erythromycin resistance was transferred from *S. citri* strain M4 Er-1 to *S. citri* R8A2+ by alkali cation plus polyethylene glycol treatment, the transfer was associated with transfer of plasmid pM42 (Salvado et al., 1989). Polyethylene glycol also induced fusion between pairs of mollicutes, including spiroplasmas (Tarshis et al., 1991). Fusion of

spiroplasmas with large unilamellar vesicles containing DNA has been used for transformation of *S. floricola*, a non-phytopathogenic mollicute that colonizes flower surfaces (Salman et al., 1992; Salman et al., 1993). Transformation by conjugal transfer from species such as *Enterococcus faecalis* has been reported for *Mycoplasma* species but not for any *Spiroplasma* species (Renaudin et al., 2002).

Electroporation now serves as a standard way of transfecting spiroplasma with phage DNA (Gasparich et al., 1993). Electroporation (McCammon et al., 1990) of a plasmid bearing transposon Tn*4001* resulted in insertion of the transposon in *S. citri* strain GII3 (Foissac et al., 1996) but not in several other strains (Foissac et al., 1997). A wide variation in the susceptibility of *S. citri* strains to electroporation-mediated transformation may be due to DNA methylation (McCammon et al., 1990). Transfection has been used in other experimental applications: for example, to demonstrate that the RF of SpV4, cloned in an *E. coli* plasmid vector, was infectious after restriction and circularization (Pascarel-Devilder et al., 1986). *Spiroplasma citri* transformed with a plasmid bearing a *Mycoplasma* sequence was used as an internal control for detecting the mycoplasma by PCR (Verdin et al., 2000).

MARKERS AND SELECTION. The successful construction of transformation vectors requires the availability of marker genes for selection. *Spiroplasma citri* mutants resistant to arsenic acid, vanadium oxide, and xylitol have been isolated (Barroso and Labarere, 1988; Barroso et al., 1990), but of these only xylitol resistance was useful in selection schemes. The chloramphenicol acetyltransferase gene, when introduced using SpV1-R8A2 B RF as a vector, was expressed in spiroplasma (Stamburski et al., 1991), but other antibiotic markers have proven more useful (S. Duret and J. Renaudin, cited in Renaudin, 2002). Resistance to tetracycline and gentamycin, encoded by the *tetM* gene of Tn*916* and the transposon Tn*4001*, respectively, have been used to select transformants of *S. citri* (Stamburski et al., 1991; Foissac et al., 1997).

VECTOR CONSTRUCTION. Genetically useful transformation of spiroplasmas also required the development of vectors capable of stable, independent replication in spiroplasmas. Vector development has proven challenging. In an effort to construct a plasmid vector, pCT-1 (an 11-kb extrachromosomal element from the non-phytopathogenic *S. taiwanense*) was characterized by restriction mapping and cloned in pBR322 (Gasparich and Hackett, 1994). The replicative form of the SpV1 phage was used as a vector to try to express a foreign gene in *S. citri* (Marais et al., 1993), but expression was complicated by recombination of the vector with

chromosomally located sequences (Marais et al., 1996).

Inactivation of *S. citri* genes by homologous recombination has been accomplished via the development of specific vectors such as the plasmid pBOT1, which is capable of replicating in *E. coli* (Renaudin et al., 1995). Owing to the presence of a spiroplasma chromosomal origin of replication, *oriC*, pBOT1 also replicates in *Spiroplasma*. It was tested for the ability to inactivate a gene required for motility (Duret et al., 1999), previously inferred to exist by the creation of motility mutants following nitrous acid treatment of *S. melliferum* (Cohen et al., 1989). One problem with pBOT1 as a gene inactivation vehicle was the presence of a large segment containing *oriC*. This region was itself susceptible to homologous recombination, leading to integration of the plasmid not in the target gene but in the *oriC* region. In an improved vector, pC2, the *oriC* region was trimmed to contain only the sequences needed for its replication (Lartigue et al., 2002). The resulting plasmid is active in several mycoplasma species as well as in spiroplasmas (Lartigue et al., 2003). One derivative, pC1/2, retains the ability to replicate in *S. citri* but appears to have lost the ability to recombine with the homologous chromosomal sequence (S. Duret and J Renaudin, cited in Renaudin, 2002).

pBOT1 has proven useful in producing gene addition lines. The additions usually are used to test whether an isolated gene provides the function missing in a mutant line. For example, insertion via an *oriC* vector of the fructose operon restored ability to use fructose and pathogenicity to a Tn*4001* nonpathogenic mutant (Gaurivaud et al., 2000). Similarly, insertion of a wildtype *scm1* gene restored motility to a mutant in which that gene had been disrupted (Jacob et al., 1997).

EXPRESSION OF SPIROPLASMA GENES IN OTHER ORGANISMS. Despite the codon differences between spiroplasmas and other bacteria (see the section General Characteristics in this Chapter), spiroplasma genes have been expressed in other organisms. An attempt was made to express the *S. citri* spiralin gene from a *Lactobacillus* plasmid in *Acholeplasma laidlawii* (Jarhede et al., 1995), but the spiralin synthesized was not processed and was made in lower than expected amounts. Plasmid pMH1 from *S. citri* has been cloned in *E. coli* as a chimera with pBR328 (Mouches et al., 1983b).

Insect Transmission

Leafhopper Feeding Behavior

Spiroplasmas and other phloem-restricted mollicutes are introduced into phloem when

inoculative vectors pierce the sieve element and subsequently salivate into the cell. This process is quite complex; successful phloem ingestion is the culmination of a series of events.

To acquire and then inoculate plant pathogenic spiroplasmas, leafhoppers must negotiate their flexible stylets through plant tissues and ultimately locate the phloem. Once a leafhopper lands on a potential host plant, the labrum is brought into contact with the plant surface. Mechanical and gustatory cues coming from mechano- and chemosensory organs assist the insect to orient over a vein. Small quantities of sheath saliva are secreted onto the plant surface through which plant chemicals diffuse and are detected by the insect's chemosensilla (Backus, 1985). The stylet tips are inserted into the plant epidermis and small quantities of plant cell contents are imbibed. If the cues are acceptable, the mandibular stylets remain anchored in the epidermis while the inner maxillary stylets continue to move deeper into the plant.

Leafhoppers are highly plastic with respect to the ability to probe and ingest from different plant tissues. With their stylets following an intracellular pathway on their way to the vascular tissues (Backus, 1985; Wayadande and Nault, 1993; Lett et al., 2001), deltocephaline leafhoppers have been documented, using electronic monitoring technology, to probe epidermis, mesophyll, phloem and xylem (Wayadande and Nault, 1996; Lett et al., 2001). Although relatively few species have been so monitored, some important spiroplasma vectors, *Dalbulus* spp., *Graminella* spp. (Wayadande and Nault, 1993) and *C. mbila* have been shown to display highly plastic host tissue preferences. These leafhoppers feed primarily from phloem tissues, but stylet pathways to the phloem for individual leafhoppers were often circuitous. Individuals ingested sap from other tissues for long periods before initiation of phloem contact (Wayadande and Nault, 1996). This observation suggests the possibility that phloem location behavior could be altered through plant breeding or genetic manipulation, as was accomplished for the rice host of the phloem-restricted plant virus, rice tungro (Khan and Saxena, 1985; Rapusas and Heinrichs, 1990; Wayadande, 1992).

Inoculation behavior has not been documented for spiroplasmas to the extent that it has been for other phloem-restricted pathogens, including barley yellow dwarf luteovirus (Scheller and Shukle, 1986), maize chlorotic dwarf waikavirus (Wayadande and Nault, 1993), and tomato yellow leafcurl geminivirus (Jiang et al., 1999). Presumably, because spiroplasmas are specifically found in phloem sieve elements, they are deposited there by their leafhopper vectors by salivation during phloem contact. Deposition in any other plant tissue and subsequent phloem

invasion would require that spiroplasmas have the ability to penetrate the phloem cell wall, an event that has been neither documented nor suggested. The study of phytopathogen inoculation by leafhoppers has been greatly enhanced by electronic monitoring technology. Now more widely known as electrical penetration graph (EPG) technology, a more intimate understanding of feeding activity *in situ* at the stylet tips is now possible. EPG monitors detect minute fluctuations in electrical current passing through food or salivary canals of feeding hemipterans, and represent them as waveform patterns. Two EPG patterns have been correlated with phloem probing: the x-waveform (a term that is no longer used) and the phloem ingestion pattern. The x-waveform, which has been documented for several deltocephaline leafhoppers, including several spiroplasma vectors, was suggested to represent alternating bouts of salivation and ingestion (McLean, 1977; Wayadande and Nault, 1993). Spiroplasma inoculation activity has not been specifically studied, but leafhopper salivation into the phloem sieve element has been recently documented for the *S. kunkelii* experimental vector, *C. mbila*, by EPG (Lett et al., 2001). Using a DC monitoring system, Lett et al. (2001) showed, using AC monitoring, that patterns 4 and 5, which correspond to the x-waveform and phloem ingestion patterns, are specifically associated with feeding activity in phloem sieve tubes. Furthermore, they showed that pattern 4 (x-waveform) contains components representing salivation activity. Thus, salivation into the phloem sieve tube during pattern 4 activity is the time at which spiroplasma inoculation is most likely to occur.

Spiroplasma-Leafhopper Interactions

SPIROPLASMA MOVEMENT THROUGH VECTOR. Leafhopper-transmitted spiroplasmas propagate in their vectors, requiring a 17–23-day latent period between acquisition and inoculation (Nault, 1980). Spiroplasmas are ingested during acquisition feeding, moving into the lumen of the alimentary canal. Kwon et al. (1999) showed that *S. citri* moved into the gut epithelium of the anterior midgut (filter chamber) of the vector *C. tenellus* (Fig. 5). Spiroplasmas were observed attached to the base of microvilli and in small membrane-bound vesicles near the apical plasmalemma. This same observation was made by Ammar et al. (2004) and Ozbek et al. (2003) in *Dalbulus* spp. vectors of *S. kunkelii.* Interestingly, the number of spiroplasmas observed in *S. kunkelii*-infected *Dalbulus* were much greater than observed in *S. citri*-infected *C. tenellus*, possibly reflecting the lower transmission rate observed for *S. citri* (Way-

adande and Fletcher, 1995) compared to that of *S. kunkelii* (Markham, 1983a).

Movement through insect tissues was suggested to be mediated by spiroplasma adhesins (Fletcher et al., 1998; Kwon, 1999). Spiroplasmas attach to the apical plasmalemma, initiating invagination into gut or salivary gland cells (Liu et al., 1983; Kwon et al. 1999). Recent micrographs of *S. kunkelii* invading *Dalbulus* gut epithelial cells show the presence of tip structures (Ammar et al., 2004) similar to those of *Mycoplasma* spp. that mediate host cell invasion (Rottem, 2003). A core of electron dense material at the center of the tip structure is clearly visible when spiroplasmas are in contact with insect plasmalemma, but less so once spiroplasmas are completely engulfed. Ammar et al. (2004) and Ozbek et al. (2003) also report the presence, on the surface of *S. kunkelii*, of pili-like structures, which in other bacteria serve as surface attachment structures (see the section Morphology in this Chapter). How spiroplasmas cross the basal lamina of gut epithelial cells to reach the hemolymph and again at the salivary gland-hemolymph interface has been the subject of much speculation. Kwon et al. (1999) showed that *C. tenellus* basal lamina becomes degenerated and less coherent as a result of spiroplasma infection, suggesting that the pleomorphic spiroplasmas could squeeze through to the hemolymph. Ozbek et al. (2003), however, presented micrographs clearly showing breaks in *D. maidis* basal lamina, and spiroplasmas apparently moving through to the hemolymph.

Spiroplasma adhesion and movement into vector host cells is thought to be mediated by cell surface proteins. *Spiroplasma citri* line BR3 protein P89, later designated "SARP1," was implicated in cell surface adhesion to vector cell line cells, an event that was blocked by prior treatment of spiroplasmas with the proteases trypsin and proteinase-K and restored after removal of the enzymes (Yu et al. 1998). The amino acid sequence of SARP1 was similar to that of a known adhesin of *Mycoplasma agalactiae* (Fleury et al., 2002). Interestingly, versions of SARP1 are found on both the chromosome and a 13-kb plasmid of *S. citri* (Joshi et al., 2004), and also in *S. kunkelii* (Davis et al., 2004). The N-terminal regions of SARP1 consist of a series of six or seven 40-residue repeats, designated "sarpins," that are found in a scattered diversity of other bacterial proteins (Berg et al., 2001). Although line BR3 has only a single plasmid bearing the *arp1* gene (Joshi et al., 2004), Foissac et al. (2004) recently showed that line GII3 has six plasmids, five of which contain a total of seven *arp* homologs. Berho et al. (2004) recently showed that the GII3 SARP protein P82 (SARP4a) had strong similarity to the BR3

SARP1. Direct evidence that the SARP proteins are directly involved in transmission await gene inactivation and complementation studies.

Other spiroplasma proteins are also implicated in the transmission process. As suggested by Boutareaud et al. (2004), the movement of spiroplasmas through the insect (crossing gut barriers, multiplication in the vector tissues, and crossing salivary gland barriers) likely involves several spiroplasma proteins. The requirement for adhesin-type proteins is well documented for several *Mycoplasma* spp. (Rottem, 2003). Other transmission related proteins recently identified include the GII3 plasmid-encoded protein, P32 (which is present on both transmissible and poorly transmissible *S. citri* lines but absent from nontransmissible lines; Killiny, 2004) and a solute binding protein of an ABC reporter (Boutareaud et al. 2004). Finally, spiralin, the dominant spiroplasma surface protein, was recently shown to be required for transmission (Duret et al., 2003). Although the mechanism of spiralin involvement is unknown, its ubiquitous distribution on the outer membrane of spiroplasmas (Morley, 1988) is consistent with a possible adhesion function. This putative function was recently supported by Killiny et al. (2004) who demonstrated that isolated spiralin protein binds to glycoproteins, a feature common among adhesins. However, other proteins are very likely involved, as loss of transmission has not always been correlated with presence or absence of spiralin. Natural *S. citri* mutants BR3-G and BR3-P, which are no longer insect transmissible or are very poorly transmitted, still express spiralin (Fletcher et al., 1995). The functions of intact spiralin and these other proteins and their specific roles in the transmission process are important foci of ongoing studies.

There have been no reports of vertical transmission of spiroplasmas to the offspring of infected females, but there have been a few reports of transovarially transmitted phytoplasmas. Alma et al. (1997) and Hanboonsong et al. (2002) both report vertical transmission of aster yellows and sugarcane white leaf phytoplasmas, respectively, through infection of leafhopper eggs. Detection of these phytoplasmas in eggs and resulting offspring was by nested PCR. This type of detection always carries the possibility that the egg was contaminated with phytoplasmas adhering to the chorion, but the possibility of transovarial transmission of mollicutes remains intriguing. Convincing demonstration of spiroplasma transovarial transmission will likely include PCR detection, transmission of spiroplasmas by offspring isolated as eggs, and transmission electron micrographs of spiroplasmas within the ova.

SPIROPLASMA PATHOGENICITY TO INSECT HOSTS. Spiroplasma infection may have an impact upon the physiology of the vector. After acquisition by the leafhopper, spiroplasma (both *S. citri* and *S. kunkelii*) titers dropped initially, but rebounded in vivo, reflecting multiplication within insect hosts. Spiroplasmas or spiroplasma-like bodies were seen in various tissues including gut epithelia, hemolymph, Malpighian tubules, fat body, neural tissue, muscle, and salivary glands (Liu et al., 1983; Markham, 1983a; Kwon et al., 1999; Osbek et al. 2003; Ammar et al. 2004). Negative impacts of *S. citri* on its vector *C. tenellus* included severe cytopathology of insect tissues (Kwon et al., 1999), including degeneration of salivary gland cells, disorganization of muscle fibers, and compromised cell integrity. In addition, leafhopper longevity and fecundity were reduced after acquisition of *S. kunkelii* (Granados, 1975; Vega et al., 1975; Ebbert and Nault, 1994). These observations have not been coupled with reports of significantly reduced vector competency or flight activity, however. In fact, early reports of the impact of spiroplasmas on their vectors suggested that pathogenicity was slight or nonexistent after injection (Whitcomb et al., 1974). There may even be some benefit to an insect carrying a population of spiroplasmas. Ebbert and Nault (2001) demonstrated that *S. kunkelii*-infected *D. maidis* were able to withstand drier overwintering conditions than were their uninfected counterparts. So, although spiroplasma infection may be detrimental to individuals under optimal growth conditions, environmental stressors may shift the selective advantage to infected populations.

Epidemiology

Factors affecting the spread and distribution of insect-transmitted plant pathogens include vector abundance, proportion of the population capable of transmitting the pathogen, and plant-to-plant dispersal (Irwin and Ruesink, 1986). The primary vectors of both *S. citri* and *S. kunkelii* (Table 1) are abundant in regions where these pathogens are prevalent, becoming more so as reproductive plant hosts become more available year round. Spiroplasma-susceptible plant hosts are more likely to serve as feeding hosts in areas where inoculating vectors occur in higher numbers as opposed to areas with low vector densities. What motivates inoculative vectors to move to a new host? The propensity of the spiroplasma vectors to move from one plant to another is affected by several factors including plant homogeneity (Power, 1988; Power, 1992; Castro et al., 1992), plant spacing (Power, 1992), diel periodicity (Kersting and Baspinar, 1995), and vector

gender. Studies of spacing and composition of spiroplasma hosts within a field indicate that closely spaced, homogeneous plantings are more likely to promote insect movement. Power (1988) suggested that genetically diverse plantings of maize were less attractive than pure stands to colonizing *Dalbulus* leafhoppers. This phenomenon may have resulted from the genetically diverse stands being suboptimal reproductive hosts or from greater emigration. Within monocultures, leafhoppers move more frequently between closely spaced plants (Power, 1992). This is consistent with the findings of Castro et al. (1992), who showed greater flight activity within maize monocultures than in maize-bean bicultures. They also compared *S. kunkelii* incidence with maize densities but found few differences.

Diel periodicity (flight activity during a 24-h period) and gender may also influence spiroplasma spread throughout a field. For example, males of the *S. kunkelii* experimental vector *Graminella nigrifrons* transmit the maize chlorotic dwarf waikavirus more readily than do females, primarily because males move from plant to plant in search of virgin females. In this "call-fly strategy," males communicate acoustically with females on adjacent plants. Males fly short distances, intermittently calling and feeding on virus-susceptible tissues (Hunt et al. 1993). This strategy was suggested to explain the fact that sticky traps placed in sesame plantings sustained higher numbers of male *C. haematoceps* (the European vector of *S. citri*) than of females, indicating greater male crepuscular flight activity (Kersting and Baspinar, 1995). Since many leafhoppers, including those in the genus *Dalbulus*, exhibit similar acoustic behavior (Heady and Nault, 1986), the call-fly strategy likely influences *S. kunkelii* spread by male, inoculative *D. maidis*.

The *Circulifer* vectors of *S. citri* are polyphagous, feeding on a number of annual and perennial hosts, many of which are *S. citri* plant hosts (Oldfield, 1988). Lowered *C. tenellus* discrimination among plant hosts or simply the insects' ability to locate and feed from the phloem of a number of plant species, such as citrus, that are poor long-term maintenance hosts (Cook, 1967), may explain, in part, why this species is able to inoculate *S. citri* to such a wide range of plant hosts. The genus *Circulifer* contains the best-documented vectors of *S. citri* and is one of the most important vector taxa because other pathogens transmitted by this group, most notably beet curly top geminivirus, are very significant (Klein, 1992). However, other *S. citri* vector species also deserve continued attention. Although most initial infections of citrus may occur by *C. tenellus* feeding after acquisition from weed hosts,

within-grove (citrus to citrus) spread may involve leafhoppers of the genus *Scaphytopius*, which reproduce on citrus (Oldfield, 1988). Early studies of the contributions of *Scaphytopius* spp. in *S. citri* epidemiology have not been continued because of limited resources and personnel working with these spiroplasma vectors.

Disease

Symptoms

Spiroplasmas incite at least three economically important plant diseases: corn stunt, caused by *S. kunkelii,* and citrus "stubborn" and brittle root disease of horseradish, caused by *S. citri*. *Spiroplasma phoeniceum*, a third plant pathogenic species, was isolated from periwinkle plants placed in a citrus orchard to serve as sentries for *S. citri*. The periwinkle plants developed symptoms similar to those induced by *S. citri*, but spiroplasmas cultured from such plants proved to be a new species (Saillard et al., 1986). Although *S. phoeniceum* has since been characterized, its natural host(s) remain cryptic.

Plant phloem presents a highly specialized environment for growth and multiplication of spiroplasmas. These mollicutes colonize and multiply to high titers in plant host sieve tubes, comprised of vertical columns of sieve cells, specialized living cells that lose their nuclei upon maturation and rely on adjacent phloem companion cells for various nucleus-directed activities. Porous sieve plates separate one sieve cell from another within each column, and spiroplasmas pass readily through these pores. They are probably carried along with photosynthates, which are produced in the chlorophyll-rich leaves and stems and translocated through the sieve tubes to non-green "sinks," plant parts such as flowers, fruits, storage organs, roots and expanding leaves (Kloepper et al., 1982). For example, *S. citri*, inoculated into turnip seedlings by confining inoculative *C. tenellus* on designated leaves, were recovered from roots four days before they were found in noninoculated leaves (Fletcher and Eastman, 1984a). Similarly, when inoculative *D. maidis* were confined on the first true leaf of corn seedlings, *S. kunkelii* moved into roots, developing leaves, and tassels over time (Gussie et al., 1995). Spiroplasma titers are often highest in actively growing tissues such as shoot tips. The phloem environment is highly suitable as a spiroplasma growth medium, providing both nourishment and an osmotically suitable milieu for these wall-less (and thus osmotically fragile) microbes.

CORN STUNT. This is one of the most costly diseases of *Zea mays* in countries of the Western Hemisphere (Nault et al., 1979). Although the condition originally was attributed to a single virus, it is now known to be a disease complex in which *S. kunkelii,* one or more of several viruses (maize rayado fino and maize chlorotic dwarf viruses), and a phytoplasma (most of which are transmitted by the same leafhopper vectors) may be involved. What was known as the Rio Grande form of the disease (Maramorosch, 1955) is now recognized as the syndrome produced by *S. kunkelii* infection. The so-called "Mesa Central" version of corn stunt, now known as "maize bushy stunt," is caused by a phytoplasma of the same name (Nault, 1980). Symptoms of the spiroplasma-induced stunt disease, which appear about 6 weeks after infection, include the appearance of small chlorotic stripes at the leaf base. The stripes lengthen and widen, eventually merging together. Symptoms vary in nature and intensity depending on the time of inoculation. In maize cultivars normally having significant levels of reddish anthocyanin pigments, irregular reddish or purplish areas may be present. Affected plants have shortened internodes, giving rise to the "stunt" phase of the disease. Proliferation of lateral shoots and roots, and excessive tillering, give the plants a bushy appearance. The numbers of ears may be greater, but they are smaller and often are sterile or have very few kernels. These symptoms may be altered or masked, however, in the case of mixed infections of *S. kunkelii* with the other pathogens mentioned above.

CITRUS STUBBORN. The name of this disease was coined in 1921 by a citrus grower frustrated with the slow growth of healthy buds grafted onto symptomatic trees (Calavan and Bové, 1989). Symptoms elicited in citrus by *S. citri* vary with the host variety and environmental conditions but generally are more pronounced on young trees (most trees become symptomatic within 5–6 years of planting) and under high temperature conditions (Calavan and Bové, 1989). The impact may be mild initially, but trees grow more slowly and become stunted compared to healthy trees of the same age planted nearby. Shortened internodes, multiple buds, and prolific shoot growth give the tree a dense, bushy appearance. New leaves are often smaller in size (the disease in Israel has been called "little leaf"), may be deformed (with a curled and mottled appearance), and may drop prematurely. Twig die-back and bark thickening are common. Like the leaves, flowers too may be reduced in size, although they are of normal appearance and color, lacking any form of the virescence (petal greening) or phyllody (leaf-shaped petals) that are commonly seen in phytoplasma-induced diseases. Fruits are often crooked and elongated, with a curved axis, and

Fig. 7. Horseradish (*Armoracea rusticana*) showing symptoms of brittle root disease caused by *Spiroplasma citri*. Panel A: foliar chlorosis and necrosis. Panel B: field of affected horseradish in southern Illinois during 1979 epidemic. Panel C: sections of diseased root showing phloem necrosis. Photos: C. E. Eastman (A, B) and N. Simkus (C), Illinois Natural History Survey, Champaign, IL.

the peel may be thinner than normal or thick and "cheesy." Greening of the style end is common, and "blue albedo," a bluish discoloration in the albedo of the peel, is sometimes seen. Seeds of affected fruits may abort. Flowers and fruit may be more numerous on affected trees, but early fruit abscission causes reduced yield. In advanced stages, affected branches wilt and the tree becomes weakened and highly vulnerable to other pathogens and stresses.

HORSERADISH BRITTLE ROOT. This disease is first apparent as foliar chlorosis, with leaves often bright golden yellow (Fig. 7). Young leaves may be stunted, leaf edges may curl and become necrotic, and leaf asymmetry may occur. The entire plant becomes stunted, wilting may occur, and foliage ultimately turns brown and decays. Root cross-sections show a yellowish-tan internal ring, caused by necrosis of the phloem, and take on a brittle quality from which the disease name is derived (Fletcher et al., 1981). Plants infected late in the season may remain symptom-free, but root pieces planted the following year usually develop brittle root symptoms and die soon after foliar emergence. A devastating epidemic in the late 1970s caused unprecedented losses and prompted an intensive

research initiative culminating in the completion of Koch's postulates demonstrating the causal agent to be *S. citri* (Fletcher et al., 1981; Raju et al., 1981b).

Losses and Impact

CORN STUNT DISEASE. The condition now recognized as corn stunt disease was first reported in the Rio Grande Valley of Texas by G. E. Alstatt in 1945 (Alstatt, 1945) and became widespread and very destructive throughout the Neotropics where corn is grown. The fact that multiple pathogens could co-infect maize (see the section Symptoms: Corn Stunt in this Chapter), causing variations in symptom syndromes and impact, caused some confusion about disease etiology, geographical range, and epidemiology during the 1950s–1970s. However, the spiroplasma-incited corn stunt disease is now known to occur in all countries where the vector occurs, from the southern United States to Argentina (Whitcomb, 1989), and is one of the most costly maize diseases in those locations (Bradfute et al., 1981; Tsai and Falk, 1988). In Texas, as much as 30% of corn fields were affected in the 1940s (Alstatt, 1945), and in Flor-

ida, a pathogen complex including *S. kunkelii* led to the loss of hybrid seed production and breeding nurseries, a $60 million enterprise, in 1979 and 1980 (Bradfute et al., 1981). Losses in the tropics can be even higher, nearing 100% in severe epidemics (Whitcomb, 1989).

CITRUS STUBBORN DISEASE. Unproductive navel orange trees showing symptoms of stubborn disease were first noted during a 3-year study (1915–1917) near Redlands, California, but the disease was so prevalent at that time that the pathogen probably was present in the United States by the turn of the century (Calavan and Bové, 1989). The first published disease description, however, came in 1928 when Reichert reported an epidemic of citrus "little-leaf" disease in Palestine. Again, the death of thousands of trees in this epidemic suggests that the pathogen had been present for a number of years. In the late 1950s and early 1960s, citrus stubborn had reached huge acreages of orchards, including many citrus species, in California. By then, Calavan (1969) estimated the number of diseased trees in California alone at about a million. The disease continued to spread, ultimately affecting from 50–100% of the trees in some orchards, and in total over 2 million trees were lost (Lee et al., 1973). The range of citrus stubborn also continued to increase in the Mediterranean region during this period, affecting many citrus species in Morocco, Algeria, Tunisia, Lebanon, Syria, Turkey and Corsica during the 1950s. By the late 1960s, it had been diagnosed in most countries of northern Africa and the Middle East (Calavan and Bové, 1989).

HORSERADISH BRITTLE ROOT. Horseradish, *Armoracia rusticana*, is a specialty crop produced commercially in southern Illinois (Fletcher et al., 1981; Fletcher, 1983). Reported first in 1936, brittle root disease has occurred sporadically in subsequent years and is considered the most important disease of the crop. Although its incidence is usually fairly low, it occasionally reaches epidemic proportions, causing 100% losses for individual growers and 25–80% loss to the horseradish industry in the state. In 1983, the disease was found in low incidence in horseradish fields in Maryland (Davis and Fletcher, 1983), expanding significantly the geographical range of the pathogen.

Virulence Mechanisms

The mechanisms by which spiroplasmas colonize and cause disease symptoms in host plants may be complex, involving a number of different virulence strategies.

PHLOEM DYSFUNCTION. Some of the symptoms induced by spiroplasma colonization of sieve tube elements reflect interruption of normal phloem activity and the resulting effects on transport of photosynthates from sites of production to sink tissues including roots, flowers, growing tips, and fruits (Fletcher, 2001). Foliar chlorosis, reduction of the sizes of plant organs, stunting and wilting, phloem discoloration and necrosis, and eventual plant death, may result from active or passive spiroplasma roles. Although a given sieve tube cell may harbor few spiroplasmas, others may support as many as 10^{13}/ml (Daniels et al., 1982), a population level that must surely impact normal phloem function as the pathogen usurps nutrients intended for plant functions and may also affect the rate of sugar transport within the phloem. Foliar and stem chlorosis may be caused by the lack of photosynthates, which could result from spiroplasma competition for phloem sugars, or by the secretion of spiroplasma substances that cause chlorophyll degeneration. The major sugar in plant phloem is sucrose, a disaccharide of glucose and fructose. Although each of these monosaccharides can be metabolized by spiroplasmas when present unconjugated, the disaccharide sucrose cannot (Bové et al., 2003). Enzymes for sugar metabolism may play an important role in spiroplasma virulence (see the section Virulence Mechanisms: Sugar Metabolism in this Chapter).

CHEMICAL IMBALANCES: NUTRIENT COMPETITIION, PLANT GROWTH REGULATORS AND INHIBITORS. Plant stunting, internode shortening, and leaf size reduction could result from nutrient reduction caused by competition between spiroplasmas and their host cells for the sugars and other elements present in phloem sap (Chang, 1989). There also is evidence for significant accumulation of lactic acid in spiroplasma growth media (Saglio et al., 1973). If similar accumulation occurs also in planta, it could inhibit normal plant functions. Stubborn-affected citrus trees exhibited higher concentrations of linalool, a leaf oil (Scora et al., 1972), and altered levels of certain organic acids (Bové et al., 1961), but the significance of these findings is unclear.

A number of symptoms caused by spiroplasma infection, including stunting and chlorosis, resemble those caused by an imbalance of host plant growth regulators. Chang, using *S. citri*- or aster yellows phytoplasma (AYP)-infected periwinkle shoot and root tip cultures to examine such interactions, demonstrated that the concentrations of auxin and cytokinin required for maximum shoot proliferation in the two groups differed significantly, indicating that the two mollicutes cause different changes in the endogenous levels of these hormones (Chang, 1989; Chang, 1998). *Spiroplasma citri*-infected tissues also sustained a greater reduction than AYP-

infected ones in the auxins required for optimal root development. Sterols, which are intermediates in many growth regulator synthetic pathways, may be usurped by the invading spiroplasmas, which require sterols for growth. Chang (1998) also investigated levels of pigment production in periwinkle plants infected with either *S. citri* or AYP. A large reduction measured in the levels of the carotenoid pigments in periwinkle plants infected with both mollicutes was consistent with the chlorosis often seen with both diseases, although concentrations of carotenoids in spiroplasma-infected leaves alone were not affected. *Spiroplasma citri* infection also resulted in lowered levels of the red- and purple-hued anthocyanin pigments.

TOXINS. At least one spiroplasma, *S. citri*, causes wilting and death of its plant hosts (citrus, horseradish and periwinkle). These symptoms appear rapidly after the necrosis and degeneration of the plant roots, and are probably due to the failure of the plant to uptake water. The involvement of a spiroplasma toxin has been suggested as the cause of root death, and in fact an *S. citri* toxin was shown to affect the physiology of tobacco leaf discs and a green alga (Daniels et al., 1973), but since the toxin's instability prevented its characterization, the question of whether toxins play a role in natural infections remains unanswered. Another factor related to water availability in mollicute infected plants is stomatal closure (Matteoni and Sinclair, 1983). Measured as the diffusive resistance to water of the leaf surface, stomatal closure was a prominent plant reaction to infection by both phytoplasmas and *S. kunkelii*, suggesting that it is a general symptom of yellows diseases. Further, the degree of closure was proportional to symptom severity. For corn plants infected with *S. kunkelii,* stomatal closure was significantly greater within the white-striped areas of leaves than in the green areas. Cytopathology was also reported in the affected corn leaves; epidermal cells within the white stripes did not elongate normally, most of the guard cells failed to differentiate completely, and infected leaves had more than twice as many stomata per unit area than healthy leaves. The physiological explanation for the stomatal effects is not known, but the authors noted that closed guard cells accumulate abscisic acid, a growth regulator associated with leaf yellowing and early leaf drop. Stomatal closure also would reduce CO_2 uptake, cause a rise in temperature in the affected tissues, and possibly inhibit xylem transport. Other cytopathic effects were noted by Overman et al. (1992), who found that the guard cells in *S. kunkelii*-infected plants had an unusual rounded morphology, and that associated cells fused with the adjacent epidermal cells.

SECRETORY SYSTEMS. Proteins secreted into the external milieu of the spiroplasmas are key candidates for involvement in host-pathogen interactions. As expected, knowledge of the complete genome sequence of *S. kunkelii* has allowed the identification of genes encoding proteins whose signal peptides contain motifs associated with transport functions, leading to the prediction of at least four protein secretion mechanisms, including a Sec-dependent pathway, a type IV secretion system, a twin-arginine mechanism, and an ABC transporter system (Zhao et al., 2004). The latter of these systems contains ATP-binding cassette (ABC) domains in 11 membrane-associated and multicomponent transporters involved in import and export of substances related to nutrition, drug resistance, and possibly virulence. Two other ABC domains occur in cytosolic systems having roles in DNA repair and response to oxidative stress. *Spiroplasma citri* also contains gene systems related to transport and secretion. The anticipated public release of the *S. citri* genome sequence (Foissac et al., 2004) will facilitate searches for additional secretion or signaling pathway genes.

PILI AND FIMBRIAE. As mentioned in the section Morphology, recent electron microscopy studies of the morphology of *S. kunkelii* revealed the presence of long, narrow surface appendages that were interpreted to be fimbriae and pili (Ozbek et al., 2003; Ammar et al., 2004; Bai et al., 2004). Similar surface appendages on other bacteria have been implicated in a number of different functions, some of which (such as recognition and attachment to host surfaces, uptake or delivery of pathogenesis- or defense-related DNA or proteins) may be involved in virulence. On the other hand, the authors (Ammar et al., 2004) noted that the surface structures seen in the micrographs could be spiroplasma viruses. Their size ranges are compatible with the latter explanation.

TRA GENES AND FUNCTIONS. Genes homologous to *traE* genes of other bacteria have recently been reported in both *S. citri* (Foissac et al., 2004; Joshi et al., 2004) and *S. kunkelii* (Bai et al., 2004; Zhou et al., 2004). Zhou et al. (2004) identified a 14.6-kb *S. kunkelii* CR2-3X plasmid, pSKU146, containing *tra*-like genes, as well as a homolog of the *S. citri* adherence-related gene *arp*, first reported by Berg et al. (2001). Joshi et al. (2004) found that the *S. citri* BR3-3X *arp* gene was located on a high copy number plasmid, the 13-kb pBJS. The same plasmid also carried open reading frames homologous to *soj*, a gene associated with chromosome partitioning, and *traE* and *mob*, two genes that, in other bacterial species, have roles in ATP-dependent DNA transfer and mobilization. The *S. citri* gene, *arp2*, a partial homolog of *arp1* that encodes a similar protein,

SARP2, is chromosomally encoded (Joshi et al., 2004). Both *tra* and *soj* genes were predicted from the sequences of six putative plasmids, pSci1–pSci6, of *S. citri* strain GII3 (Foissac et al., 2004). The presence of genes such as *tra*, *mob*, *soj* and *arp* on plasmids may contribute to the acquisition and stability of the plasmid in spiroplasmas, in addition to contributing to their leafhopper transmissibility and plant pathogenicity. Two *tra* genes and *arp*-related genes identified in another *S. kunkelii* strain, M2, were located on a plasmid (Bai et al., 2004). Predicted protein products of the M2-associated *tra* genes had transmembrane regions and ATPase domains.

SUGAR METABOLISM. Although metabolic capabilities are not usually considered virulence factors, aspects of sugar metabolism have been identified as central to the pathogenicity of *S. citri* (Gaurivaud et al., 2000; Gaurivaud et al., 2001; Bové and Garnier, 2002; Bové et al., 2003). Spiroplasmas residing in phloem sieve tubes use glucose and fructose as major sources of energy. When insertion of a transposon into the *S. citri* genome led to a mutant displaying reduced pathogenicity, the interrupted gene was identified as *fru*R, the first gene in an operon involved in fructose utilization. Other genes in the operon include *fru*A, encoding fructose permease, and *fru*K, encoding 1-phosphofructokinase, both of which contribute to the spiriroplasmas' ability to utilize fructose as an energy source. The *fru*R mutants, unable to utilize fructose, induced symptoms much later than wildtype spiroplasmas, and the symptoms were mild. Bové and Garnier (2002), noting that the fructose concentration in sieve tubes is normally low while sucrose concentrations are very high, speculated that sucrose loading by companion cells is fructose-dependent. Utilization of this low-abundance sugar by spiroplasmas would cause impairment of sucrose loading into sieve tubes, resulting in symptoms such as slower plant growth and chlorosis. The fact that *fru*R mutants still induced mild symptoms indicated that fructose metabolism is not the only factor in spiroplasma pathogenicity.

The regulation of the fructose operon also is relevant to the spiroplasma's niche adaptation (Gaurivaud et al., 2000). Expression of *fru*R is upregulated in the presence of fructose, and the FruR protein is an activator of the operon. Interestingly, when spiroplasmas colonize the hemolymph of their insect vectors, where trehalose, rather than glucose and fructose, is the most prevalent sugar, they begin to metabolize the trehalose instead. The organization of the spiroplasma operon for trehalose utilization is very similar to that of the glucose and fructose operons. Andre et al. (2003) characterized the permease II enzymes (EII^{Glc} and EII^{Tre}) of the *S. citri*

phosphoenolpyruvate:glucose and phosphoenolpyruvate:trehalose phosphotransferase systems (PTS). The former contains three domains distributed in two cistrons (A and BC), all necessary for activity. EII^{Tre} lacks the A cistron, whose function is supplied by that of EII^{Glc}. Andre et al. speculated that the ability of the EII^{Glc} A cistron to function with both the glucose and trehalose permeases might be an adaptive strategy, allowing the spiroplasmas to convert their sugar utilization strategies efficiently during the niche changes associated with transmission to a new host (see also the section Physiology and Metabolism in this Chapter).

PHYTOPATHOGEN-UNIQUE SEQUENCES. The availability of the genome sequences of several phytopathogenic mollicutes allowed the recent identification of putative phytopathogenicity-related genes common to three phytopathogens: the aster yellows (AY) phytoplasma, the onion yellows (OY) phytoplasma, and *S. kunkelii* (Bai et al., 2004). These species were not among the obligate animal or human pathogenic mollicutes for which genomic sequences were available. The proteins putatively encoded by these four genes unique to the plant pathogens included a polynucleotide phosphorylase, an exoribonuclease of the PDX family, which, in other bacteria, is involved in mRNA degradation and the regulation of genes associated with invasion and multiplication. In the insect-transmitted mollicutes of plants, the frequent movement between the plant and insect hosts may require such enzymes for rapid adaptation to the alternative niches. A second putative protein has similarity to the C-repeat binding factor (CBF) gene of *Staphylococcus aureus*, which binds to a *cmp* DNA sequence to facilitate plasmid replication. A third, a cytosine deaminase, functions in nucleotide metabolism and protein synthesis. A fourth putative protein resembles YlxR, a protein that binds to RNA and is suggested to be involved in gene expression. This study provides an example of the types of information that will become even more available and useful as the number of complete genome sequences increases.

HOST REACTIONS. The colonization of the very specialized phloem sieve tubes by the phytopathogenic mollicutes in general, and by spiroplasmas in particular, raises the question of whether such infections set off plant defense responses such as the production of reactive oxygen species, polyphenols, phytoalexins, signaling cascades, etc., that are commonly activated following infection by nonvascular pathogens. Also unclear is whether plant pathogenic vascular-limited prokaryotes are detected by plant host sensors in a manner that causes activation of defense pathways. If such defense reactions are

initiated, researchers do not know whether defense-associated molecules are delivered into phloem sieve tubes, or, if they are, whether mollicutes are affected by them. However, maize cultivars resistant to corn stunt spiroplasma are available.

In 2001, Jagoueix-Eveillard et al. examined plant mRNAs that were up- or downregulated following infection of periwinkle with one of three mollicutes, *S. citri*, Candidatus *Phytoplasma aurantifolia*, and the stolbur phytoplasma. Of the 24 differentially expressed cDNAs chosen for study, 8 were similar to known genes encoding proteins related to photosynthesis, sugar transport, stress responses, and sterol biosynthesis. One gene induced in periwinkle by *S. citri*, and known to be induced in *Arabidopsis* by salicylic acid (He et al., 1999), encodes a plant defense-related cell wall-associated kinase. Jagoueix-Eveillard and colleagues reported that the defense reactions observed could not be correlated with particular pathogens but could be associated with the production of particular symptoms.

Control

Our current ability to manage spiroplasma diseases of plants is limited and is best approached with a multi-pronged approach (Fletcher, 2001b).

Traditional Methods

Corn stunt disease, affecting an annual crop, has been managed by several methods including eradication of affected plants, field sanitation, and removal of alternate hosts (*Tripsacum* sp; Tsai and Miller, 1995). In many parts of the world, maize is grown in various intercropped systems, often with beans and sometimes also with cucurbits (cucumbers, melons, pumpkins and squash). Maize diseases caused by insect transmitted viruses may be less severe in their impact in intercropped fields, possibly because of altered crop-insect dynamics related to plant density and diversity. To investigate the hypothesis that the same might be true for maize bushy stunt phytoplasma and the corn stunt spiroplasma, Castro et al. (1992) measured disease incidence and pathogen identity in several maize-bean intercropped field designs (Fig. 8), but no difference in disease incidence was found.

Management of citrus stubborn disease is somewhat more challenging because of the perennial nature of the crop and the high value of individual trees. Recommendations include the location of citrus nurseries in regions having little or no spread of *S. citri*, selection of propa-
Fig. 8. Maize-soybean intercropping in Costa Rica. Photo: M. E. Irwin, Illinois Natural History Survey, Champaign, IL.

gation scions from healthy trees, elimination of brassicaceous weed hosts from field borders and groves, regular inspection of nurseries and groves, and roguing of infected plants (Fletcher, 2001a).

Because of the sporadic nature of horseradish brittle root disease, little is known about the effectiveness of cultural methods to control the disease. Since the vector *Circulifer tenellus* thrives best in hot, dry, exposed field areas, irrigation of affected fields may reduce drought stress on plants and make the fields less hospitable for beet leafhopper reproduction and development. After a brittle root outbreak, horseradish growers should take care to select healthy root cuttings for planting the following year to minimize carryover of the spiroplasma. Roguing plants that become symptomatic early in the season (likely to have grown from cryptically infected root cuttings) may minimize infield spread.

Host Resistance

In some cases, germplasm encoding natural resistance to spiroplasmas or their vectors is available, and such genes are incorporated into breeding programs for high-value crops, vegetables and fruits, and ornamentals (Fletcher, 1999). Additional resistance genes may be found in wild

progenitors of crop species or in other plants. Plant defense chemicals are known to be involved in host defense reactions against other pathogens, but whether such chemicals are effective against mollicutes, and whether they are delivered to phloem sieve tubes, remain unanswered questions. Only a few investigators have explored the differential expression of plant genes in the presence of mollicutes. See the section Virulence Mechanisms in this Chapter.

Chemical Treatments

Antibiotic treatments have been of some usefulness for management of "yellows" diseases in non-food plants of high value, such as ornamentals (Sinha, 1979; McCoy and Williams, 1982). The efficacy of certain antibiotics against spiroplasmas depends on their pore forming ability (Beven et al., 1999). The methyl ester of amphotericin B was effective against *S. citri* in culture (Goldstein et al., 1976). Penicillins and other antibiotics that interfere with bacterial cell wall

synthesis have no effect on the wall-less mollicutes. Antibiotics in the tetracycline family, with a mode of action related to interference with protein and nucleic acid synthesis, are most effective. Chloramphenicol was somewhat less effective when tested for control of phytoplasma diseases. Treatment often leads to temporary remission of symptoms, an effect that persists for varying periods depending on the method of application, which may include spraying, root or shoot dips, or vascular infusion. Tetracycline is translocated in the xylem, becoming systemically distributed and apparently ultimately being uploaded into the phloem. Unfortunately, symptoms reappear soon after suspension of treatment, and antibiotic treatments have the added concern of residues in plants used for food and feed (Sinha, 1979; Fletcher, 2001). Tetracyclines have not proven beneficial in citrus (Fletcher, 2001a). Interestingly, streptomycins are effective against *S. citri* in culture but not in planta (McCoy and Williams, 1982). Although this antibiotic moves through the plant in the xylem, it apparently is not phloem-mobile. Few examples of successful management of spiroplasma diseases by chemicals other than antibiotics exist,

but quinine and quinoline compounds protected fruit trees against another mollicute, the X-disease phytoplasma (Sinha, 1979).

Insect Management

Managing spiroplasma vectors through the use of insecticides is challenging because the insects must be killed before they feed on host plants. However, epidemiological considerations may make insect control effective under some conditions. In California citrus production areas, the elimination of potential vector species in weedy areas prior to weed removal will prevent insect migration into adjacent citrus groves (Oldfield, 1984). Extensive use of insecticides may have reduced the incidence of horseradish brittle root disease in epidemic years, possibly by reducing secondary spread from brittle root affected to healthy plants (Fletcher et al., 1981). Recently, when investigating a significant incidence of corn stunt disease sustained in silage corn production in the southern San Joaquin Valley, California, Frate et al. (2004) found that seed treatments with the systemic insecticides (imidacloprid and clothianidin) significantly reduced both the numbers of vector leafhoppers, *D. maidis*, and the incidence of stunt disease.

Plantibodies

The fact that monoclonal and polyclonal anti-spiroplasma antibodies inhibit the pathogens' growth and metabolism in vitro led investigators to hypothesize that transgenic plants, engineered to express such antibodies, would be disease resistant. Noting that recombinant single-chain variable fragment (scFv) antibodies were excellent candidates for expression in plants, Chen and Chen (1998) demonstrated that scFv antibodies prepared against *S. kunkelii* were expressed in the cytoplasm of tissue cultured maize cells. However, although the cell line showed spiroplasma-binding activity, plants regenerated from the transgenic cells were indistinguishable from wild-type plants in their susceptibility to the spiroplasma. The authors speculated that the lack of resistance could have resulted from a lower inhibitory activity of the scFv antibodies compared to polyclonal or monoclonal antibodies, a lack of antibody expression at the actual spiroplasma colonization site (plant sieve tubes), or a lower level of antibody expression in the regenerated plants than in the transgenic cell line. Later, Malembic et al. (2002) demonstrated that scFv antibodies against *S. citri* were able to inhibit spiroplasma growth and motility, although significant spiroplasma growth inhibition might require a multiplexed system involving expression of two or more three such antibodies in combination. These authors also broached the possibility of delivering antibodies to plant sieve tubes using engineered, nonpathogenic spiroplasma strains.

Future Possibilities

Although our ability to manage plant diseases caused by spiroplasmas is currently very limited, significant advances in our understanding of how spiroplasmas cause plant malfunctions and interact with their insect vectors will create new possibilities for maintaining healthy plants despite the threat of spiroplasma diseases.

CHAPTER 1.3.1

The Family Heliobacteriaceae

MICHAEL T. MADIGAN

Introduction

The family Heliobacteriaceae consists of phototrophic bacteria that contain bacteriochlorophyll (Bchl) *g* (Fig. 1). This unique Bchl, found only in the heliobacteria, distinguishes them from all other anoxygenic phototrophic bacteria (Madigan, 2001; Madigan and Ormerod, 1995b). The heliobacteria were discovered in a very serendipitous fashion by Howard Gest and Jeff Favinger in the early 1980s; a fascinating account of this discovery can be found in Gest (1994). The unique characteristics of heliobacteria were first revealed a few years later with publication of the description of *Heliobacterium chlorum* (Gest and Favinger, 1983) and the structure of Bchl *g* (Brockmann and Lipinski, 1983). Subsequent research in the Gest laboratory led to the discovery of *Heliobacillus*, and with this, the establishment of the family Heliobacteriaceae (Beer-Romero and Gest, 1987). Four genera of heliobacteria are currently recognized: *Heliobacterium*, *Heliobacillus*, *Heliophilum* and *Heliorestis* (Madigan, 2001).

Besides producing Bchl *g*, heliobacteria can also be distinguished from all other anoxygenic phototrophs by their lack of differentiated photosynthetic internal membranes, such as the membrane vesicles or lamellae of purple bacteria or the chlorosomes of green bacteria. As far as has been determined, photosynthetic complexes in heliobacteria reside in the cytoplasmic membrane (Miller et al., 1986). Heliobacteria are also phylogenetically distinct anoxygenic phototrophs. They group with the low G+C Gram-positive bacteria; specifically, with endosporulating bacteria such as *Clostridium* species (Madigan, 2001; Woese et al., 1985).

Bacteriochlorophyll *g* shows structural relationships with both chlorophyll *a* and with the various bacteriochlorophylls of green and purple bacteria (Brockmann and Lipinski, 1983; Michalski et al., 1987). Like green plant chlorophyll *a* but unlike all bacteriochlorophylls, Bchl *g* contains a vinyl ($H_2C=CH_2$) group on ring I of the porphyrin tetrapyrrole. However, like bacteriochlorophylls *a* and *b* and unlike chlorophyll *a*,

pyrrole ring II of Bchl *g* is reduced (Brockmann and Lipinski, 1983; Fig. 1). Moreover, the esterifying alcohol of Bchl *g* is farnesol (Michalski et al., 1987), the alcohol that also esterifies the bacteriochlorophylls of green sulfur bacteria (Gloe et al., 1975), instead of the phytol or geranylgeraniol found in Bchls *a* and *b* or the phytol of green plant chlorophylls (Oelze, 1985).

The novel bacteriochlorophyll of heliobacteria is responsible for the unique absorption properties of these phototrophs. Heliobacteria absorb maximally in the near infrared at 788 nm (Fig. 2), distinctly away from regions of the spectrum absorbed by green bacteria and purple bacteria; the latter groups typically show near infrared absorption maxima at 705–740 nm or 830–1100 nm, respectively (Oelze, 1985). The absorption maximum of Bchl *g* represents a "window" in the spectrum of all other phototrophic organisms (Madigan, 1988; Pfennig, 1989) and this characteristic undoubtedly contributes to the ecological success of the heliobacteria in nature.

The photosynthetic reaction center of heliobacteria is contained along with associated antenna pigments in a single pigment-protein complex (Amesz, 1995). And, although the primary photosynthetic electron donor in heliobacteria is Bchl *g*, the primary electron acceptor is a form of chlorophyll (not bacteriochlorophyll) *a* called hydroxychlorophyll *a* (Amesz, 1995). This and other molecular features of heliobacterial photocomplexes (Amesz, 1995) highlight the structural (and thus phylogenetic) relationship between them and green plant photosystem I (Amesz, 1995; Gupta et al., 1999; Schubert et al., 1998; Stackebrandt et al., 1996). Molecular comparisons of pigment biosynthesis genes further support a close phylogenetic connection between the heliobacteria and oxygenic phototrophs (Xiong et al., 2000).

Besides its unique Bchl, heliobacteria also synthesize novel carotenoids. Although heliobacteria were originally thought to contain only a single carotenoid (the C_{40} pigment neurosporene; Van Dorssen et al., 1985), a reexamination of the carotenoids of several species of heliobacteria has shown that there are mainly
Fig. 1. Structures of bacteriochlorophyll *g* (top) and chlorophyll *a* (bottom). Note that both pigments are structurally identical on rings I and II except that ring II (shaded in both structures) is reduced in bacteriochlorophyll *g* (Bchl *g*). Also note that the esterifying alcohols are farnesol in Bchl *g* and phytol in chlorophyll *a*.
Fig. 2. Absorption spectrum of intact cells of the thermophilic heliobacterium, *Heliobacterium modesticaldum*. Solid line, cells suspended in 30% bovine serum albumin that was reduced by adding 0.05% ascorbate. Dashed line, spectrum of the same cell suspension exposed to light and air for one hour. Note major peak of bacteriochlorophyll *g* at 788 nm and of chlorophyll *a* at 670 nm (L. K. Kimble and M. T. Madigan, unpublished observations).
five structurally related C_{30} carotenoids spectrally resembling neurosporene and only traces of neurosporene itself; the pigment 4,4'-diaponeurosporene predominates in all species examined (Takaichi et al., 1997; Fig. 3). The synthesis of C_{30} carotenoids is another feature that makes heliobacteria unique from a photosynthetic perspective; carotenoids in all other phototrophic organisms are C_{40} derivatives (Takaichi, 1999; Takaichi et al., 1997).

Fig. 3. Carotenoids of heliobacteria. Neurosporene (C_{40}) is present in only trace amounts in heliobacteria while the remaining pigments (all C_{30} carotenoids) are present in larger amounts. Of the five C_{30} pigments shown, 4, 4′diaponeurosporene (shown in bold) was the dominant carotenoid found in five species of heliobacteria examined. (From Takaichi et al., 1997, with permission.)

Phylogeny

The phylogeny of heliobacteria (as deduced from comparative 16S ribosomal RNA sequencing) places them within the low G+C Gram-positive bacteria (Woese, 1987), specifically within the clade containing the endosporulating rod-shaped bacteria *Bacillus* and *Clostridium* (Madigan, 2001; Woese et al., 1985). The four known genera of heliobacteria (Table 1) form a rather tight cluster near the reductive dechlorinating organism *Desulfitobacterium dehalogenens* (Fig. 4). Lying basal to all known heliobacteria is *Heliorestis daurensis*, a morphologically and physiologically unique species (Bryantseva et al., 1999; see Habitat; Fig. 4).

Although the basis for the phylogenetic connection between phototrophic heliobacteria and nonphototrophic endosporulating anaerobes remains obscure, the grouping of the heliobacteria with the latter, first proposed in 1985 by Woese et al. (1985), was indeed prophetic. As might have been predicted from their phylogenetic position, heliobacteria were later discovered to produce endospores (see Taxonomy); like those of *Bacillus* and *Clostridium* species, heliobacterial endospores were shown to contain elevated levels of Ca^{2+} and dipicolinic acid (Ormerod et al., 1990; Ormerod et al., 1996).

The Gram-positive connection between heliobacteria and clostridia is enigmatic, as it concerns cell wall structure and chemistry. Unlike typical clostridia, heliobacteria contain rather thin cell walls and actually stain Gram-negatively; however, no evidence for a lipopolysaccharide (LPS)

outer membrane has been obtained (Beer-Romero et al., 1988; Madigan, 2001). By contrast, several truly Gram-positive features of heliobacteria cell walls are apparent and include peptidoglycan containing L, L- diaminopimelic acid (instead of *meso*-diaminopimelic acid) in muramic acid cross-links, and the presence of a glycine interbridge (Beer-Romero et al., 1988; Pickett et al., 1994).

Fatty acid and cytochrome analyses of heliobacteria have also strengthened their Gram-positive connection. Heliobacteria contain a high proportion of branched-chain fatty acids, a common feature of Gram-positive bacteria, with up to 60% of the fatty acids in various species being branched-chained; of the latter, isopalmitoleic acid typically predominates (Beck et al., 1980). Moreover, molecular analyses of the dominant *c*-type cytochrome in heliobacteria, cytochrome c_{553}, have shown it to be closely related to the homologous protein from *Bacillus* species (Albert et al., 1998).

In summary, grouping of the heliobacteria with other low G+C Gram-positive bacteria is supported by 1) comparative ribosomal RNA sequencing, 2) the production of endospores, 3) certain but not all aspects of cell wall chemistry, 4) fatty acid composition, and 5) cytochrome *c* type. Other connections between heliobacteria and Gram-positive bacteria, especially the clostridia, will become apparent in the sections on Habitat and Physiology.

Taxonomy

Four genera with a total of seven species are currently officially recognized within the family Heliobacteriaceae (Madigan, 2001). The genus *Heliobacterium* and the species *H. chlorum* (Fig. 5) was the first of the heliobacteria to be discovered, but for various reasons, including the tendency for cells of this species to lyse when reaching late exponential phase (Gest and Favinger, 1983), it is not the major species worked with today. The genus *Heliophilum* is unusual because its cells form bundles that move as a unit (Fig. 6).

Most species of heliobacteria are rod-shaped, typically with tapered cell ends (Fig. 7), and are motile by flagellar means (Fig. 8). Cells of *Heliobacterium gestii* are spiral-shaped (Bryantseva et al., 1999). Cells of heliobacteria show no remarkable fine structure, as no differentiated photosynthetic membrane systems of any type are apparent (Fig. 9). All heliobacteria have genus names that begin with "Helio," a combining form from the Greek word "helios," meaning "sun." A summary of the major properties of described species of heliobacteria is presented in Table 1.
Fig. 4. Phylogenetic tree of heliobacteria based on comparative 16S rRNA sequences and analysis by parsimony. (From Bryantseva et al., 1999, with permission.)

Table 1. Summary of properties of heliobacteria.

Property	Heliobacterium chlorum	Heliobacterium gestii	Heliobacterium modesticaldum	Heliobacillus mobilis	Heliophilum fasciatum	Heliorestis daurensis	Heliorestis baculata
Habitat	Temperate soil	Tropical paddy soil	Neutral/alkaline hot springs and volcanic soils	Tropical paddy soil	Tropical paddy soil	Microbial mats of brackish soda lakes	Soda lake shoreline soil
Morphology	Rod	Spirillum	Rod/curved rod	Rod	Straight rods with tapered ends grouped in bundles of two to many cells	Coiled to bent rod or short filament	Rod
Dimensions	1×7–$9\mu m^a$	1×7–$10\mu m^b$	0.8–1×2.5–$9\mu m^c$	1×7–$10\mu m$	0.8–$1\mu m \times 5$–$8\mu m$	0.8–$1.2\mu m \times 10$–$20\mu m$	0.6–$1\mu m \times 6$–$10\mu m$
Motility	Gliding	Multiple subpolar flagella	Flagellar or none	Peritrichous flagella	Polar to sub-polar flagella; cell bundles move as a unit	Peritrichous flagella	Peritrichous flagella
Carbon sources photo-metabolized	Pyruvate, lactate and yeast extract	Pyruvate, lactate, acetate, butyrate, ethanol ($+CO_2$), yeast extract, glucose and fructose	Pyruvate, lactate, acetate and yeast extract	Pyruvate, lactate, acetate, butyrate ($+CO_2$) and yeast extract	Pyruvate, lactate, acetate and butyrate ($+CO_2$)	Pyruvate, acetate and yeast extract	Pyruvate, acetate and yeast extract
Biosynthetic sulfur sources	SO_4^{2-}, $S_2O_3^{2-}$, methionine, or cysteine	$S_2O_3^{2-}$, methionine, or cysteine	$S_2O_3^{2-}$, sulfide, methionine, or cysteine	SO_4^{2-}, $S_2O_3^{2-}$, methionine, or cysteine	SO_4^{2-}, $S_2O_3^{2-}$	Sulfide	Sulfide
Endospores[d]	None observed	Yes	Yes	None observed	Yes	Yes	Yes
Optimum temperature, °C	37–42	37–42	50–52	38–42	37–40	30	30
Optimum pH	7	7	6–7	6.5–7	6.5–7	9	8.5–9.5
Mol% G+C content	52	55.1	54.6–55	50.3	51.8	44.9	45

Rudi Turner.) B) Longitudinal section of a cell of Heliobacterium modesticaldum strain Ice1. Note absence of intracytoplasmic membranes. Marker bars: A, 0.25 µm; B, 1 µm.

Habitat

Since heliobacteria were first discovered, considerable evidence has accumulated to suggest that soil, in particular rice (paddy) soil, is their major habitat. This goes back to the original isolation of *Heliobacterium chlorum* from garden soil (Gest and Favinger, 1983), and to the subsequent isolations of *Heliobacillus mobilis* (Beer-Romero and Gest, 1987) and *Heliobacterium gestii* and *Heliophilum fasciatum* (Ormerod et al., 1996) from paddy soils.

In a study of potential heliobacterial habitats, 29 of 159 soil, mud or water samples were found to be positive for heliobacteria by enrichment culture assay, and 13 of these enrichments yielded pure cultures (Stevenson et al., 1997). By contrast, none of the water or sediment samples, including both freshwater and marine sources, contained culturable heliobacteria. Notably, many of the driest soil samples tested were the most successful in enrichment cultures for helio-bacteria (Stevenson et al., 1997). This result is likely due to recovery of heliobacterial

endospores rather than to the presence of actual vegetative cells of heliobacteria in these extremely dry soils.

Although the study of Stevenson et al. (1997) did not exhaustively test aquatic habitats for heliobacteria, the fact that none of the aquatic samples tested (except for hot spring waters, see following paragraph) yielded these organisms, suggests that unlike green and purple bacteria (Madigan, 1988; Pfennig, 1989), heliobacteria are not common (or are perhaps even absent) in lakes, ponds and other aquatic environments. The caveat is, of course, that this conclusion is based on data obtained solely from successful or unsuccessful enrichment cultures. Thus the range of habitats of the heliobacteria is still an open question and needs input from other methods such as environmental sampling with specific nucleic acid probes. For example, although everything points to soil as the habitat of helio-bacteria, it is possible that physiologically distinct heliobacteria exist in aquatic habitats whose enrichment requires special conditions not yet understood.

The only exception to the finding that helio-bacteria are soil residents is the discovery of extremophilic heliobacteria in submersed microbial mats. The thermophilic species *Heliobacterium modesticaldum* is widespread in neutral to alkaline hot spring microbial mats (Kimble et al., 1995; Stevenson et al., 1997). Pure cultures of several strains of *H. modesticaldum* grow up to 57°C (optimum 52°C; Kimble et al., 1995) and positive enrichments for this organism were obtained from samples taken at temperatures as high as 70°C (Stevenson et al., 1997).

The alkaliphilic heliobacteria *Heliorestis daurensis* (Bryantseva et al., 1999) and *Heliorestis baculata* (Bryantseva et al., 2000) were also isolated from microbial mats, in this case from mats and soil along the shores of Lake Barun Torey, a soda lake located in the South Chita region of Siberia (Russia). This lake is unusual because of its alkalinity (~pH 9) and low salinity. *Heliorestis daurensis* could be enriched from both cyanobacterial mats surrounding the lake and from soils of dried lagoons adjacent to the lake. Subsequent isolation of *H. baculata*, an alkaliphilic heliobacterium phylogenetically related to *H. daurensis*, was made from soda lake soil near to the mats (Bryantseva et al., 2000). The discoveries of *H. modesticaldum* and the soda lake heliobacteria thus leave open the possibility that freshwater or marine microbial mats also could be habitats for heliobacteria.

Isolation

Enrichment and isolation of heliobacteria begins with an appropriate inoculum. As described in

the Habitat section, soils (especially paddy soils) are good sources of heliobacteria. Indeed, even very dry paddy soil can contain culturable heliobacteria (Stevenson et al., 1997). A variety of media, both defined and complex, have been successful for the enrichment of heliobacteria. But in most cases an additional step in the enrichment process, pasteurization (80°C, 15 min) of the inoculum, has been the key to successful enrichments of heliobacteria (Stevenson et al., 1997). Presumably, heating kills vegetative cells of competing organisms leaving heliobacterial spores to germinate in the semiselective media.

Because heliobacteria are rather strict anaerobes, all media used for their isolation must first be rendered anoxic, such as by boiling the medium for 5 min under a stream of nitrogen and carbon dioxide ($N_2:CO_2$ [95:5]) and then transferring 10-ml aliquots to 25-ml anoxic tubes and sealing under anoxic gas with rubber stoppers. The tubes are then secured in a tube press (Bellco®) and autoclaved for 20 min. Enrichment cultures are established by adding 0.25–0.5 g of sample to 10 ml of anoxic enrichment medium and then vigorously sparging the headspace with $N_2:CO_2$ (95:5) for 30 s and sealing (enrichments to be pasteurized need to have their stoppers wired down before heating). Enrichments should be incubated at 30–40°C (except for thermophilic enrichments, incubated at 48–52°C) and a light intensity of 40–60 $\mu g \cdot m^{-2} \cdot sec^{-1}$ incandescent illumination.

Positive enrichments for heliobacteria are signaled by a green color and spectral evidence for Bchl *g* (Figs. 1 and 2). Liquid from such an enrichment should then be transferred to plates of 0.25% (w/v) yeast extract or pyruvate mineral salts (PMS) medium or pyruvate yeast extract (PYE) medium within an anoxic chamber and streaked for isolation with sterile disposable inoculating loops. Streaked plates can then be incubated in anoxic jars and incubated photosynthetically at the appropriate temperature. For further details on procedures for the enrichment and isolation of heliobacteria, the interested reader should consult the paper by Stevenson et al. (1997).

Culture Media

Enrichments for heliobacteria can be established in a 0.25% (w/v) yeast extract liquid medium or in various defined or even complex media. Pure cultures (except for the alkaliphiles *H. daurensis* and *H. baculata*) typically grow well in medium PMS or PYE. These media can also be used for enrichment and isolation of heliobacteria but have the disadvantage that they also support good growth of a variety of nonphototrophic fermentative bacteria as well.

For most species of heliobacteria that have been isolated thus far, warm (~40°C) enrichment temperatures and high light intensities seem to favor their development and help to select against nonsulfur purple bacteria; the latter can be major competitors in heliobacterial enrichments if moist soil/mud or sediments are used as inocula. Because most heliobacteria also fix N_2 (Kimble and Madigan, 1992a; Kimble and Madigan, 1992b; Stevenson et al., 1997), deleting the ammonia from medium PMS (or its variations) makes it more selective for heliobacteria, especially if the pasteurization step is also employed. Medium PYE is a rich medium that supports luxuriant growth of most pure cultures of heliobacteria, but it is not particularly successful in primary enrichments.

Media Recipes

The following (not commercially available) formulations are mentioned in this chapter.

Pyruvate Mineral Salts (PMS) Medium

The following ingredients are added to 1 liter of double-distilled water:

EDTA	10 mg
$MgSO_4 \cdot 7H_2O$	200 mg
$CaCl_2 \cdot 2H_2O$	75 mg
NH_4Cl	1 g
K_2HPO_4	0.9 g
KH_2PO_4	0.6 g
Sodium pyruvate	2.2 g
Trace element solution (see below)	1 ml
Biotin	15 μg
Vitamin B_{12}	20 μg

Adjust the pH to 6.8 with NaOH or HCl and sterilize by autoclaving for 20 min. After cooling briefly, add either methionine, cysteine or thiosulfate to a final concentration of 1 mM and transfer to an anoxic chamber until used. If thiosulfate is used, it can be added to the medium prior to autoclaving.

Modified PMS Media

1) LMS medium is pyruvate-free PMS medium containing sodium lactate at a final concentration of 20 mM.

2) AMS medium is pyruvate-free PMS medium containing 20 mM sodium acetate plus 0.1% (w/v) $NaHCO_3$.

3) PMS-N medium is PMS medium minus NH_4Cl. The gas in the headspace of the enrichment should be $N_2:CO_2$ (95:5). This medium is suitable for enrichments using nitrogen fixation as a selective tool.

Mixed Acid Mineral Salts (MAMS) Medium

This semi-defined enrichment medium avoids the use of pyruvate and contains three less easily fermented organic acids. The following are added to 1 liter of distilled water:

EDTA	10 mg
NaCl	0.4 g
$MgSO_4 \cdot 7H_2O$	200 mg

CaCl$_2$ · 2H$_2$O	75 mg
NH$_4$Cl	0.8 g
K$_2$HPO$_4$	0.45 g
KH$_2$PO$_4$	0.3 g
NaHCO$_3$	1 g
Trace elements solution (see below)	1 ml
Yeast extract	0.2 g
Vitamin B$_{12}$	20 µg
Sodium acetate	1 g
Sodium malate	2 g
Sodium lactate	1 g

Adjust the pH to 6.8 and sterilize by autoclaving for 20 min. Add (after cooling) NaHCO$_3$ from a filter-sterilized stock solution and either methionine, cysteine or thiosulfate to a final concentration of 1 mM and transfer to an anoxic chamber until used. If thiosulfate is used, it can be added to the medium prior to autoclaving.

Modified MAMS (MAMS-N) Medium MAMS medium minus NH$_4$Cl (MAMS-N) is suitable for heliobacteria and other anoxygenic phototroph enrichments using N$_2$-fixation as a selective tool (Gest et al., 1985). The headspace of enrichment should be filled with N$_2$:CO$_2$ (95:5).

Pyruvate-Yeast Extract (PYE) Medium

This medium is suitable for growth of pure cultures of all species of heliobacteria except those of *Heliorestis*. The following are added to 1 liter of double-distilled water.

K$_2$HPO$_4$	1 g
MgSO$_4$ · 7H$_2$O	200 mg
CaCl$_2$ · 2H$_2$O	20 mg
Na$_2$S$_2$O$_3$ · 5H$_2$O	100 mg
Sodium pyruvate	2.2 g
Yeast extract	4 g

Adjust to pH 7, autoclave, and store in sealed tubes or bottles in an anoxic chamber until used. Alternatively, 1–2 mM sulfide can be added (final pH 6.8) and media dispensed to sterile and completely filled screw-cap tubes or bottles.

Medium Hr for Growth of *Heliorestis daurensis* and *Heliorestis baculata*

For enrichment and culture of alkaliphilic heliobacteria, a modification (designated medium Hr) of the medium described by Bryantseva et al. (1999) is appropriate.

Distilled water	0.6 liter
EDTA	5 mg
Trace elements	1 ml
KH$_2$PO$_4$	0.5 g
NH$_4$Cl	0.5 g
MgSO$_4$ · 7H$_2$O	0.2 g
CaCl$_2$ · 7H$_2$O	75 mg
Na$_2$CO$_3$	2.5 g
NaHCO$_3$	2.5 g
Na acetate	1 g
Yeast extract	0.1 g
Na$_2$S · 9H$_2$O	0.5 g

The carbonate and bicarbonate are autoclaved dry in a 0.5–1-liter bottle and dissolved in 300 ml of sterile distilled water after autoclaving; this solution is then added to the main nutrient solution with gentle stirring. Sulfide is prepared as a separate solution (100 ml) and also added to the main solution after autoclaving. The main salts solution is prepared in a 2–10-liter dispensing jar containing a spigot for dispensing media into tubes or bottles. After autoclaving, all solutions are mixed and the pH is adjusted with sterile HCl or NaOH to 9–9.5; the final assembled medium is immediately dispensed to completely fill screw-cap tubes or bottles and then capped tightly. A slight grayish-black precipitate forms in the medium.

Trace Element Solution for All Heliobacteria Media

The following are added to 1 liter of distilled water:

EDTA (sodium salt)	5.2 g
FeCl$_2$ · 4H$_2$O	1.5 g
ZnCl$_2$	70 mg
MnCl$_2$ · 4H$_2$O	100 mg
H$_3$BO$_3$	6 mg
CoCl$_2$ · 6H$_2$O	190 mg
CuCl$_2$ · 2H$_2$O	17 mg
NiCl$_2$ · 6H$_2$O	25 mg
Na$_2$MoO$_4$·2H$_2$O	188 mg
VSO$_4$ · 2H$_2$O	30 mg
NaWO$_4$ · 2H$_2$O	2 mg

Add compounds in the above order; ethylene diamine tetraacetic acid (EDTA) should be fully dissolved before adding the other components. Store at 4°C.

Growth Vessels

Growth of pure cultures of heliobacteria can be accomplished in either neoprene rubber-stoppered culture tubes (for example, 18 × 142 mm Bellco® anoxic culture tubes), or in screw-cap tubes or bottles; if sulfide is not used, more reliable growth is achieved in stoppered tubes. Screw-cap tubes or bottles should be filled completely and tightly capped. However, because the seal of screw-cap vessels is rarely perfect, growth of heliobacteria requires the addition of 0.05% (w/v; final concentration) of sodium ascorbate. Alternatively, 1–2 mM (final concentration) of sulfide is a good reductant and has not been found growth inhibitory with most species. The best method of media preparation using rubber-stoppered tubes is to add boiled nonsterile media to anoxic culture tubes while constantly degassing with an anoxic gas mixture (N$_2$:CO$_2$, 95:5, previously passed through a hot, reduced copper furnace to remove all traces of O$_2$) and sealing each tube under an atmosphere of anoxic gas. Tubes (containing about an equal volume of medium and gas headspace) are stoppered and then autoclaved in a tube press. Sterile tubes can be stored outside the anoxic glove box and inoculated using standard "Hungate-type" techniques.

Identification

The major identifying feature of species of Heliobacteriaceae is the presence of Bchl *g* (Fig. 1). Organisms containing Bchl *g* show in vivo absorption maxima at 788–790 nm (Fig. 2; see also Table 1). However, one must be very cautious in interpreting spectra from heliobacterial enrichment cultures because of the ease with which Bchl *g* is converted to a form of chlorophyll *a* upon exposure to oxygen and light; this conversion greatly affects absorption spectra (Beer-Romero et al., 1988, see also Fig. 2). For example, the small peak at 670 nm, which is always present in spectra of heliobacteria and presumably due to the hydroxychlorophyll *a* in their reaction center (Amesz, 1995), can become the major peak following exposure of intact cells to light in air (Fig. 2). This is a problem, of course, because it could lead one to erroneously conclude that the enrichment contained cyanobacteria instead of heliobacteria. Thus, the best way to perform spectra on cells from enrichment cultures (or pure cultures for that matter) is to transfer cells directly into a pre-reduced (0.05% ascorbate) viscous medium (60% w/v sucrose or 30% w/v bovine serum albumin) within an anoxic glove box. Following this, the mixture should be transferred to a cuvette within the glove box, mixed well, and then removed from the glove box, and the spectrum recorded immediately. As previously mentioned, definitive determination of Bchl *g* is proof that one has enriched species of Heliobacteriaceae.

On plates, colonies of heliobacteria are brown green in color and show either a flattened or slightly raised center with entire or spreading margins, depending on the strain (Stevenson et al., 1997; Fig. 10). However, because of the Bchl *g* → chlorophyll *a* transition mentioned above, colonies of heliobacteria will, like liquid cultures, change color from brown green to emerald green within an hour or so of exposure to air; during this time, cell viability decreases significantly.

Cells of species of heliobacteria are fairly large rods, 1 μm × 6–10 μm (Figs. 5–9). Cells of the alkaliphile *Heliorestis daurensis* form short filaments 8–20 μm long (Bryantseva et al., 1999; Fig. 11). Most isolates of heliobacteria are motile by flagellar means, either polar, subpolar or peritrichous (Fig. 8). In young pure cultures or in enrichments, slowly motile cells can be observed by phase microscopy. These tend to stop moving within a half-hour or so, probably because of oxygen toxicity. Cultures of many heliobacteria form spheroplasts in early stationary phase and so nonmotile rounded structures are commonly observed microscopically. Further features for identifying species of heliobacteria include the following: Gram-stain (negative); electron
Fig. 10. Colonies of heliobacteria. A) Colonies of strain THAI 15P1, which produces nonspreading colonies with entire margins. B) Colonies of strain THAI 13P1, which produces spreading colonies with irregular margins. Cells of both strains were grown phototrophically on plates of medium PYE. Marker bars, 3 μm. (From Stevenson et al., 1997, with permission.)
Fig. 11. Phase-contrast photomicrograph of cells of *Heliorestis daurensis* strain BT-H1. Cells are long rods to short filaments that display a slow swimming motility. Marker bar, 10 μm.

microscopy (thin, often "studded" cell wall and absence of internal photosynthetic membranes, Fig. 9); and lack of aerobic growth. However, it should be reemphasized that Bchl μ*g* is the definitive, and only reliable, indicator of heliobacteria.

Endospores can apparently be produced by all heliobacteria. This conclusion rests on the fact that cloned endospore-specific genes, such as the *ssp*1 gene from *Bacillus* or *Clostridium* species (Setlow, 1988), hybridize to DNA from all heliobacteria tested (L. K. Kimble and M. T. Madigan, manuscript in preparation). Although large sporulating rods, presumably heliobacteria, are a common observation in enrichment cultures (Stevenson et al., 1997), formation of endospores in pure cultures of heliobacteria occurs only sporadically, if at all. Thus, whereas the presence or absence of sporulating cells in an enrichment should not be taken as evidence for or against successful enrichment of heliobacteria, enrichments that contain Bchl μ*g* definitely contain heliobacteria.

Preservation

For short-term (weeks to months) storage of heliobacteria, "stabs" of medium PYE can be established and incubated in the light in anoxic jars. Once fully grown, stab cultures can be stored for several months in anoxic jars or in an anoxic chamber exposed to low light. For unknown reasons, stab cultures of heliobacteria retain viability much longer than do liquid cultures stored under the same conditions.

Freezing or lyophilizing cell suspensions of heliobacteria is more problematic, but has been done successfully. For freezing, cultures grown to mid-exponential phase on medium PYE should be mixed with an equal volume of pre-reduced medium PYE containing 10% (v/v) DMSO in sterile snap-cap disposable plastic tubes, and then kept at 0°C for 10 min. Tubes should then be stored at −80°C (or lower) in a freezer or at −196°C in liquid nitrogen. Lyophilization of dense suspensions of heliobacteria by the double vial method (Gherna, 1981) apparently also has been successful (R. L. Gherna, personal communication) but the author has no direct experience with this.

Recovery of frozen cultures is by no means a sure thing. In this laboratory, successful recovery has averaged only about 50%, and thus when a strain is set up to be frozen away, several replicate vials should be prepared. To recover cells from the frozen state the entire contents of the quickly thawed suspension should be transferred immediately to an anoxic tube of medium PYE, sealed under N_2:CO_2, and the tube kept in darkness for several hours before placing it in the light. If viable cells are present, growth should commence within one week. Also, for unknown reasons, certain species of heliobacteria freeze better than others. For example, although recovery of frozen cultures of *Heliorestis daurensis* is close to 100%, recovery of frozen cells of *Heliobacillus mobilis* is much less than 50% (M. T. Madigan, unpublished observations).

Physiology

As far as is currently known, heliobacteria are obligate anaerobes. However, they can grow both photo- and chemotrophically. Phototrophic growth occurs under anoxic conditions in the light and requires organic compounds as carbon sources, and thus growth is referred to as photoheterotrophic. However, unlike purple nonsulfur bacteria, also photoheterotrophs (Madigan, 1988), heliobacteria described to date catabolize only a short list of organic substrates including pyruvate, lactate, acetate, butyrate (+CO_2), ethanol (+CO_2), and yeast extract; *Heliobacterium gestii* also photometabolizes a few sugars (Table 1).

Pyruvate is the only compound universally used by heliobacteria (Table 1). Excellent photoheterotrophic growth of all known heliobacteria can be achieved in defined media containing pyruvate and biotin as a growth factor. With a few species, a reduced sulfur source for biosynthetic purposes is also needed (Table 1). Supplementing the medium with a small amount of thiosulfate, cysteine, methionine, thioglycollate, sulfide or yeast extract can satisfy the latter.

Photoautotrophic growth has not been demonstrated with any species of heliobacteria. If these organisms truly lack an autotrophic capacity, it would be a unique situation among phototrophic organisms. Curiously, however, many heliobacteria are quite sulfide tolerant, and when significant (1–2 mM) levels of sulfide are present in photoheterotrophic media, it is oxidized to elemental sulfur during growth (the sulfur appears in the medium as it does with green sulfur bacteria). However, in the presence of sulfide and with CO–/bicarbonate as sole carbon sources, photoautotrophic growth does not occur. Molecular hydrogen (H–) also fails to support autotrophic growth.

Concerning the capacity of heliobacteria for photoautotrophy, it is significant that no hybridization was observed in Southern blots of DNA from two species of heliobacteria with a ribulose bisphosphate carboxylase (RuBisCO) probe (F. R. Tabita, personal communication). RuBisCO is the key enzyme of the Calvin cycle, a widely distributed pathway of autotrophy in phototrophic and chemolithotrophic prokary-

otes (Tabita, 1995). Thus it is possible that the lack of photoautotrophy in the heliobacteria is due to the absence of an autotrophic CO_2 fixation pathway. On the other hand, maybe an alternative autotrophic pathway exists in the heliobacteria, but the necessary conditions for expression of the genes that encode it have not been found. More work on this problem is clearly needed.

Pyruvate-dependent chemotrophic (dark) growth of heliobacteria occurs with most species (Kimble et al., 1994). Chemotrophic growth requires anoxic conditions and is optimal in heavily buffered media containing high levels of pyruvate. Medium DPYE, designed for chemotrophic growth of heliobacteria, is medium PYE (see Isolation) modified to contain a final concentration of 60 mM pyruvate, 0.4% (w/v) yeast extract, 10 mM K_2HPO_4, and 40 mM 3-(N-morpholino) propane sulfonic acid (MOPS, Sigma, St. Louis) as buffer (final pH 7.3; Kimble et al., 1994). Chemotrophically grown cells of heliobacteria are fully pigmented; thus it can be concluded that, as for purple bacteria (Bauer, 1995), anoxia is the signal for derepression of pigment synthesis in heliobacteria.

Energy conservation during chemotrophic growth of heliobacteria occurs by pyruvate fermentation. None of the other carbon sources that support photoheterotrophic growth of heliobacteria (Table 1) support chemotrophic growth. Chemotrophically grown cultures acidify the medium and analyses have shown that acetate accumulates as a product during growth on pyruvate (Pickett et al., 1994; Kimble et al., 1994). It is thus likely that chemotrophic growth of heliobacteria occurs by fermentation of pyruvate through the activity of either pyruvate:ferredoxin oxidoreductase or pyruvate:formate lyase (or both); these enzymes cleave pyruvate to generate acetyl-CoA, which can be converted to acetate with formation of ATP (Thauer et al., 1977).

Ecology

The finding that heliobacteria reside mainly in soil points to a unique ecological role for these organisms in nature. Anoxygenic purple and green bacteria are primarily aquatic organisms (Pfennig, 1989), and although they occasionally can be enriched from soils, their ecological significance outside of aquatic environments is likely minimal (Pfennig, 1989). By contrast, heliobacteria clearly reside in soil (Stevenson et al., 1997) and employ at least one excellent strategy for survival there; unlike purple and green bacteria, heliobacteria can sporulate (see Phylogeny and Taxonomy) and this capacity proba-

bly allows them to withstand periods of unfavorable growth conditions in soil.

The apparent lack of autotrophic capacities in the heliobacteria (see Physiology) means that they are likely to be most active and abundant in the rhizosphere, where organic compounds excreted from plant roots would support their photoheterotrophic lifestyle. In this connection, the discovery that heliobacteria are widespread in paddy fields (Stevenson et al., 1997) is not surprising. Indeed, perhaps a truly symbiotic relationship exists between heliobacteria and rice plants-in exchange for fixed nitrogen, heliobacteria would obtain from the rice plants the carbon sources they need for biosynthesis and N_2 fixation. Nitrogen fixation by phototrophic organisms is known to be a major process in paddy soils (Buresh et al., 1980; Habte and Alexander, 1980) and heliobacteria are strong nitrogen-fixers (Kimble and Madigan, 1992a; Kimble and Madigan, 1992b; Madigan, 1995a). Thus, some (if not much) of the N2 fixation that occurs in paddy soils may be due to heliobacteria.

Study of the possible symbiosis between plants and heliobacteria would be a good area for future experimentation using molecular techniques like polymerase chain reaction (PCR) and fluorescent-in situ-hybridization (FISH). In this connection, collaborative work from my laboratory has yielded highly specific nucleic acid probes for the heliobacteria based on signature sequences in their 16S rRNA (L. A. Achenbach, J. R. Carey and M. T. Madigan, unpublished observation); such probes could be used in both of these techniques.

As regards N_2-fixation, it also should be mentioned that some heliobacteria, in particular the species *H. gestii*, contain alternative (non-molybdenum; non-Mo) nitrogenases. The alternative system in *H. gestii* is an iron (Fe)-only (type III) nitrogenase (Kimble and Madigan, 1992b; Loveless and Bishop, 1999); such an enzyme might be very useful to heliobacteria growing in paddy fields where Fe is typically abundant but where other heavy metals, such as Mo and vanadium (V), have leached out.

An enigma surrounding the ecology of heliobacteria is why phototrophic organisms, especially obligately anaerobic phototrophs that grow best at high light intensities, would inhabit soil in the first place. One might easily predict that soils in general would greatly restrict light penetration and that in other than waterlogged soils, anoxic conditions would be localized and transitory. However, soils are known to be quite heterogeneous in their chemical and physical properties and so the combination of light, anoxic conditions, and organic compounds necessary for photoheterotrophic growth of heliobacteria may be more common than we think

(Madigan manuscript submitted to Appl. Environ. Microbiol.). Again, this is an area where molecular probing might yield some interesting results.

The ecology of heliobacteria in microbial mats is another interesting question. Using molecular probes, it should be possible to track heliobacteria through mat cores to see where these organisms are most abundant. Gradients of light and O_2 can be quite steep in microbial mats (Ward et al., 1989) and thus heliobacteria are likely to be present only in certain zones. Heliobacteria may be ecologically significant in microbial mats in terms of N_2 fixation. For example, the thermophile *H. modesticaldum* can fix N_2 up to its maximum growth temperature of 57°C (Kimble et al., 1995) and thus may contribute to the nitrogen economy of a wide variety of hot spring microbial mats.

Applications

The major application of heliobacteria thus far has been as experimental tools for biophysical and biochemical studies of photosynthesis (Amesz, 1995). The reaction center photocomplex of heliobacteria is an excellent model for green plant photosystem I, and because of this, heliobacteria have been intensely studied in terms of the details of photosynthetic electron flow (Amesz, 1995; Schubert et al., 1998). Unfortunately, no genetic transfer system exists for any species of heliobacteria. But when such is developed, the ability of heliobacteria to grow chemotrophically in darkness should allow photosynthetically incompetent mutants to be isolated and studied, as has been done extensively with purple bacteria (Bauer, 1995). This, combined with a genetic system would allow for the first genetic probing of green plant photosystem I events in a bacterial system. However, despite the absence of a genetic transfer system, much progress has already been made using cloned DNA from heliobacteria to complement mutants in other photosynthetic microorganisms (Bauer, 1995; Xiong et al, 2000). New and exciting information on the unity and diversity of photosynthesis has emerged from such studies (Xiong et al., 2000).

Future agricultural applications of heliobacteria could emerge from a better understanding of their nitrogen-fixing activities in soils. As previously mentioned (see Ecology), heliobacteria are primarily soil organisms and may thus be ecologically significant contributors of fixed nitrogen to soil ecosystems, paddy soils in particular. If this is true, then heliobacteria would be agents of soil fertility for the major food staple of over one-half the world's population. However, under any

conditions, the fact that the ecology of heliobacteria is closely linked to soil and the fact that all major representatives fix molecular nitrogen (Kimble and Madigan, 1992a; Kimble and Madigan, 1992b; Madigan, 1995a), means that heliobacteria likely possess features of interest to plant biologists and speaks well for the future agricultural significance of the group.

CHAPTER 1.3.2

Pectinatus, *Megasphaera* and *Zymophilus*

AULI HAIKARA AND ILKKA HELANDER

Introduction

First described in the late 1970s (Lee et al., 1978; Weiss et al., 1979), *Pectinatus* and *Megasphaera* are both anaerobic, Gram-negative contaminants of unpasteurized beer. The anaerobic, Gram-negative *Zymophilus*, isolated from pitching yeast, was described in 1990 along with a new *Selenomonas* sp. (Schleifer et al., 1990). The new genus and species *Pectinatus cerevisiiphilus* (Lee et al., 1978) and new species *Megasphaera cerevisiae* (Engelmann and Weiss, 1985) were proposed on the basis of genetic and phenotypic differences existing between these new isolates and related genera or species described in *Bergey's Manual of Systematic Bacteriology* (Rogosa, 1984). The new species *Pectinatus frisingensis*, although already isolated in 1978 and identified as *P. cerevisiiphilus* in 1981 (Haikara et al., 1981b), was finally established in 1990 (Schleifer et al., 1990) simultaneously with the description of a new genus comprising the two species *Zymophilus raffinosivorans* and *Zymophilus paucivorans*. Analysis by 16S rRNA sequence comparisons, DNA/DNA hybridizations and phenotypic characterization has revealed the phylogenetic positions of *Pectinatus*, *Megasphaera* and *Zymophilus*. These genera belong to the *Sporomusa* subbranch of the Gram-positive Clostridium subphylum, indicating possible Gram-positive ancestors. The genetic relationship between the species of the Gram-negative, anaerobic brewery bacteria still needs to be refined.

Their anaerobic nature largely explains the simultaneous occurrence of *Pectinatus* and *Megasphaera* species in beer (in many countries) and the detection of *Zymophilus*. The dissolved oxygen content present during brewing, particularly of beer, has decreased considerably in recent years. Minimal access to oxygen is a brewing technology advance intended to improve the important chemical stability of beer. As a consequence, these strict anaerobes are mainly encountered as contaminants in large, modern breweries equipped with effective filling tech-

nology (Chelack and Ingledew, 1987; Seidel et al., 1979). Another reason might be the growing tendency in industry to produce more "natural" beer without pasteurization. On the other hand, the most effective cleaning and disinfection practices in use have managed to eliminate more rapidly growing contaminants, thus providing growth opportunities for anaerobic beer spoilers.

Phylogeny

Pectinatus

The phylogenetic position of *Pectinatus* has been confirmed during recent years (Schleifer et al., 1990; Motoyama and Ogata, 2000b; Ludwig et al., 1992; Both et al., 1992; Willems and Collins, 1995; Sawada et al., 1999; Klugbauer et al., 1992). The 16S rRNA, 23S rRNA and the ATPase β-subunit gene sequences, the 16S-23S rDNA intergenic spacer regions as well as DNA-DNA hybridization have been used as phylogenetic markers. *Pectinatus* species, along with *Selenomonas*, *Megasphaera*, *Sporomusa*, *Veillonella* and *Zymophilus*, belong to the *Sporomusa* subbranch of the *Clostridium subphylum* of Gram-positive bacteria (Schleifer et al., 1990; Willems and Collins, 1995). Moreover, *Pectinatus* species have been classified as relatives of Gram-negative, anaerobic bacteria such as *Centipeda periodontii* (Sawada et al., 1999), *Dialister pneumosintes* (Willems and Collins, 1995), *Schwarzia succinivorans* (Van Gylswyk et al., 1997), *Acidaminococcus fermentans* (Both et al., 1992) and some *Anaerovibrio* species (Strömpl et al., 1999). According to the 16S rRNA sequences, the similarity between *P. frisingensis* and *P. cerevisiiphilus* was 95%, the nearest other species (similarities with *Pectinatus* spp.) being three *Selenomonas* species (88–89%), *Clostridium quercicolum* (87–88%), *Sporomusa paucivorans* (86–88%), *Veillonella parvula* (86–87%) and *Megasphaera elsdenii* (86%; Willems and Collins, 1995). The phylogenetic studies of Motoyama and Ogata (2000b)

showed that the 16S–23S rDNA intergenic spacer regions of two *Pectinatus* spp., two *Zymophilus* spp. and one *Selenomonas* sp. were of two molecular sizes (long and short). The DNA sequence homologies of the long spacer region indicated that *Pectinatus* spp. were more closely related to *Selenomonas lacticifex* than to *Zymophilus* spp. The dendrogram of the short spacer region, however, did not agree with that of the long spacer region, which according to the authors better reflects the phylogenetic position. Moreover, analysis of the short spacer region did not correspond to that of the 16S rRNA sequence published by Schleifer et al. (1990), who found *S. lacticifex* was more closely related to *Zymophilus* spp. than to *Pectinatus* spp. Notably, the order of the alanine tRNA/isoleucine tRNA genes present in the long spacer regions of *Pectinatus* and *Selenomonas* strains was the reverse of what was previously reported (Gürtler and Stanisich, 1996).

From 16S rRNA analysis, it is quite clear that the genus *Pectinatus* does not belong to the family Bacteroidaceae, as originally suggested (Lee et al., 1978), because the genus *Bacteroides* and related genera represent a distinct phylum within the phylogenetic tree of bacteria (Schleifer et al., 1990; Willems and Collins, 1995). The unrelatedness is also evident on the basis of the lipopolysaccharide composition of representatives of the genus *Pectinatus* (Helander et al., 1983; Helander et al., 1992).

Megasphaera

Megasphaera, like *Pectinatus*, *Zymophilus*, *Sporomusa* and *Selenomonas* species, belongs to the group of bacterial species with Gram-negative cell walls within the phylum of Gram-positive bacteria (Stackebrandt et al., 1985; Schleifer et al., 1990).

Doyle et al. (1995) have clarified the phylogenetic position of *Megasphaera cerevisiae* by determining the nucleotide sequence of the small subunit 16S rRNA of the bacterium. Analysis confirmed the phylogenetic position of *M. cerevisiae* as a sister taxon of *M. elsdenii* within the obligately anaerobic, Gram-negative cocci. The phylogenetic tree (obtained by applying the neighbor-joining method and parsimony analyses) demonstrated the relationships between *M. cerevisiae* and organisms of the *Sporomusa* group (Doyle et al., 1995).

Both et al. (1992) studied the phylogenetic position of *Acidaminococcus fermentans* in the *Sporomusa* cluster containing Gram-negative bacteria, i.e., *Sporomusa*, *Megasphaera*, *Selenomonas*, *Butyrivibrio*, *Pectinatus* and *Zymophilus*. Within this cluster, the relationship between species of *Acidaminococcus* and *Megasphaera*, described to be members of *Veillonellaceae*, was obvious but did not exclude other Gram-negative organisms. The phylogenetic analysis of *Dialister pneumosintes* (formerly *Bacteroides pneumosintes*) revealed that the closest relatives of this species within the *Sporomusa* subbranch of *Clostridium subphylum* were *Megasphaera elsdenii* and *Veillonella species* (Willems and Collins, 1995).

Zymophilus

According to the 16S rRNA nucleotide sequences, *Zymophilus* spp. belong to the *Sporomusa* subdivision of the *Clostridium subphylum* (Schleifer et al., 1990; Willems and Collins, 1995; Both et al., 1992). The similarity between two *Pectinatus* species and *Z. paucivorans* was 88%, which was also their similarity to *Selenomonas lacticifex* (Willems and Collins, 1995). On the basis of the DNA sequence homologies of long 16S-23S intergenic spacer regions, *S. lacticifex* was more closely related to *Pectinatus* spp. (51%) than to *Zymophilus* spp. (40%; Motoyama and Ogata, 2000b).

Taxonomy

Taxonomic Differentiation of *Pectinatus*

Pectinatus cerevisiiphilus was originally suggested to belong to the family Bacteroidaceae consisting of anaerobic, nonsporeforming Gram-negative rods (Lee et al., 1978) and later described in {*Bergey's Manual of Systematic Bacteriology*} (Lee, 1984). During the 1980s several genera (e.g., *Pectinatus* and *Selenomonas*) in this family underwent taxonomic revisions and, owing to their closer affinity (Schleifer et al., 1990; Willems and Collins, 1995), were transferred to the *Clostridium subphylum* of the Gram-positive bacteria.

Simultaneous with the description of the new *P. cerevisiiphilus* ATCC 29359T, another strain (VTT E-79100; later P. frisingensis ATCC 33332T) was isolated in Finland and identified as the same species on the basis of its physiological and biochemical characteristics (Haikara et al., 1981b). However, this strain as well as many other new isolates (when compared to *P. cerevisiiphilus*) showed clear-cut differences in serological characteristics (see Identification), cell-surface-protein patterns and immunoblot analysis (Haikara, 1983; Hakalehto et al., 1984; Hakalehto and Finne, 1990). DNA/DNA hybridization studies also revealed two distinct groups among *Pectinatus* strains isolated from beer (Haikara, 1989; Schleifer et al., 1990). Schleifer et al. (1990), who also described the new species

P. frisingensis, determined the similarity value of 16% between strains ATCC 29359 and ATCC 33332. Only small differences existed between the G+C content of the DNA of *Pectinatus* species/strains (38 to 41 mol%; see Physiology; Back et al., 1979; Haikara et al., 1981b; Kirchner et al., 1980; Schleifer et al., 1990).

In addition to a low degree of genotypic similarity between the two species, they could be phenotypically distinguished (Schleifer et al., 1990). Many characteristic differences were observed in the utilization of carbon sources, e.g., *P. cerevisiiphilus* degraded xylose and melibiose, but not cellobiose and *N*-acetyl-glucosamine, whereas in the case of *P. frisingensis* the situation was the reverse (see Physiology; Haikara, 1991; Schleifer et al., 1990). Moreover, Schleifer et al. (1990) amended the description of *P. cerevisiiphilus* because the phenotypic properties of *P. cerevisiiphilus* ATCC 29359 T were not in agreement with the original description (Lee et al., 1978).

Cell Envelope Components

FATTY ACIDS The cellular fatty acid composition is similar in type strains of *P. cerevisiiphilus* and *P. frisingensis*. The fatty acids are heavily dominated by odd-numbered fatty acids; 11:0, 15:0, 17:1, 18:cyc and 13:0(3-OH) were the main fatty acids detected in both species (Helander and Haikara, 1995). Alk-1-enyl chains with chain lengths of 15 to 18 also were found, indicating the presence of plasmalogens common in strict anaerobic bacteria. In addition to the major hydroxy acid component (*R*)-13:0(3-OH), both *Pectinatus* species were shown to contain, in minor amounts, five 3-hydroxy acids with chain lengths of 11 to 15 carbons. These included the unsaturated acid 13:1(3-OH), the occurrence of which is limited to *Pectinatus*. As discussed by Helander and Haikara (1995), and Strömpl et al. (1999), because fatty acid 13:0(3-OH) is not in the MIDI database utilized for fatty acid-based identification of anaerobic bacteria, this fatty acid has been erroneously identified as 14:0 dimethylacetal (DMA) in several bacterial genera, including *Pectinatus* (Moore et al., 1994).

PEPTIDOGLYCAN *Pectinatus* possesses cross-linked meso-diaminopimelic acid-containing peptidoglycan, with covalently linked diamine (cadaverine or, rarely, putrescine) in the peptide subunit of the peptidoglycan (Schleifer et al., 1990). With the aid of monoclonal antibodies isolated on the basis of their binding to *P. cerevisiiphilus* peptidoglycan, Ziola et al. (1999) found a peptidoglycan structure that they suggested was common to several species of anaerobic beer spoilage bacteria, including *P. frisingensis*, *Sele-*

nomonas lacticifix, *Zymophilus paucivorans* and *Z. raffinosivorans*.

LIPOPOLYSACCHARIDES The cell surface lipopolysaccharides (LPS) of the type strains *P. cerevisiiphilus* ATCC 29359 and *P. frisingensis* ATCC 33332 have been characterized in detail. Several exceptional properties are assigned to *Pectinatus* LPSs, including the production of at least two distinct types of LPS by one strain (Helander et al., 1992), the presence of the phosphorylated disaccharide α-D-GlcpN-(1'-4)-Kdo (3-deoxy-D-manno-oct-2-ulopyranosonic acid) in the LPS core (Helander et al., 1993), the resistance of the lipid A-polysaccharide linkage to acid (Helander et al., 1994), and the predominance of furanosidic 6-deoxyhexoses in the O-specific chains (Senchenkova et al., 1995). The lipid A backbone of *P. cerevisiiphilus* and *P. frisingensis* is composed of the common bisphosphorylated β1'-6-linked glucosamine (GlcN) disaccharide, with almost quantitative substitution of the ester-linked phosphate by 4-amino-4-deoxyarabinose (Helander et al., 1994). It was later shown that the glycosidically linked phosphate of *Pectinatus* also carries minor amounts of this aminopentose, analogous to the structure found in *Klebsiella pneumoniae* O3 lipid A (Helander et al., 1996). The fatty acids in *Pectinatus* lipid A comprises two amide-linked and two ester-linked 13:0(3-OH). The hydroksyl groups of the fatty acids linked to the non-reducing GlcN, carry the fatty acid 11:0 or, to a small extent, 13:0 in acyloxyacyl linkage. Whereas 13:0(3-OH) is the main hydroxy acid in *Pectinatus*, the minor 3-hydroxy acids are also most probably constituents of the lipid A, although their position has not been determined. Complete structures of the core oligosaccharides in *Pectinatus* LPSs are not known, but each strain presumably elaborates two structurally distinct cores, only one of which carries polymeric O-specific chains; these two LPS populations can be separated from each other during processing of initial phenol/chloroform/petroleum ether extracts (Helander et al., 1992). The O-specific chain of *P. cerevisiiphilus* is composed of repeating disaccharides of 1 → 2 linked β-D-fucofuranose and α-D-glucopyranose, whereas the repeating unit of *P. frisingensis* O-specific chain is a branched tetrasaccharide consisting of a single sugar type, the rare 6-deoxy-L-altrofuranose (Senchenkova et al., 1995). It is worthy of note that the O-specific chains of *Pectinatus* are highly labile towards acid, whereas the normally acid-labile lipid A-core linkage is exceptionally stable. The reason for the latter property is unknown at present, but the presence of acid-stable linking sugars such a 2-octulosonic acid has been excluded in *Pectinatus* LPSs (Helander et al.,

1994). The LPSs of both species of *Pectinatus* exhibit the biological potency of classical endotoxins (Helander et al., 1984).

RIBOTYPING The ribotyping fingerprinting technique has proved to be a useful tool for characterization and identification of beer spoilage bacteria (Storgårds et al., 1998; Satokari et al., 2000; Motoyama et al., 1998; Motoyama et al., 2000c; Suihko and Haikara, 2001). Motoyama et al. (1998) used three different restriction enzymes (i.e., EcoRI, HindIII and BamHI) for ribotyping of *Pectinatus cerevisiiphilus* and *P. frisingensis* strains. When a combination of all these enzymes was used, all 34 *P. frisingensis* strains fell into 1 of 17 ribotypes. Five *P. cerevisiiphilus* strains were classed as one of three types with single enzymes, the composite ribotypes not showing greater definition. Suihko and Haikara (2001) used EcoRI enzyme for characterization of 24 *P. frisingensis* and 8 *P. cerevisiiphilus* strains and used 16S rDNA sequencing of selected strains for confirming the ribotyping. *Pectinatus frisingensis* strains were divided into nine different ribotypes and *P. cerevisiiphilus* strains into five, allowing identification below the species level. Interestingly, these techniques also revealed a possible new species within the genus *Pectinatus*.

Taxonomic Differentiation of *Megasphaera*

Anaerobic Gram-negative cocci were assigned in *Bergey's Manual of Determinative Bacteriology* to the family Veillonellaceae (Rogosa, 1974). On the basis of differential characteristics of the genera *Veillonella*, *Acidaminococcus* and *Megasphaera* of this family, the beer isolates could be assigned to the genus *Megasphaera* (Weiss et al., 1979). The abilities to ferment carbohydrates and to produce volatile fatty acids containing 5–6 carbon atoms are the most distinctive characteristics of the genus *Megasphaera*. The only previously known species in this genus was a rumen microbe, *M. elsdenii* (Rogosa, 1971; Rogosa, 1984). The G+C content of the DNA of this species is 53.6 mol%. The corresponding G+C values of 12 brewery isolates ranged from 42.4 to 44.8 mol% (Table 1; Engelmann and Weiss, 1985), indicating that there is no genomic relationship between the *Megasphaera* species isolated from beer and *M. elsdenii*. DNA/DNA hybridization studies also supported this finding and showed that all isolates from beer belong to a single genospecies (Engelmann and Weiss, 1985), the similarity within this group being over 72%. Moreover, no genomic relatedness was detectable between *Veillonella parvula* and the beer isolates, and hence Engelmann and Weiss (1985) proposed a new species named *M. cerevisiae*.

The 16S ribosomal RNA gene analysis results have later confirmed the phylogenetic position of *M. cerevisiae* as a sister taxon of *M. elsdenii* within the obligately anaerobic, Gram-negative cocci and facilitated the development of specific polymerase chain reaction (PCR) primers for early detection of this spoilage organism (Doyle et al., 1995; Satokari et al., 1998; Juvonen et al., 1999; Sakamoto et al., 1997).

Composition of the Cell Envelope

FATTY ACIDS The cellular fatty acids of *M. cerevisiae* and *M. elsdenii* have been investigated, and shown to be almost identical (Johnston and Goldfine, 1982; Helander and Haikara, 1995). The main fatty acid components are 12:0, 16:0, 16:1, 18:1, 17:cyc, 19:cyc, 12:0(3-OH) and 14:0(3-OH), and alk-1-enyl chains instead of acyl chains are detected to a considerable extent (14% of

Table 1. Characteristics of Gram-negative, anaerobic genera isolated during the brewing processes.

total fatty acids); alk-1-enyl chains are indicative of plasmalogen lipids, as demonstrated previously by Kaufman et al. (Kaufman et al., 1988; Kaufman et al., 1990) for *M. elsdenii*. No information is available concerning the LPS composition of the genus *Megasphaera*.

PEPTIDOGLYCAN The cell surface protein pattern and the chemical composition of *M. cerevisiae* LPS is not known. However, Engelmann and Weiss (1985) analyzed the amino acid composition of the cell wall peptidoglycans of *Megasphaera* spp. The peptidoglycan of *M. cerevisiae* as well as that of *M. elsdenii* was of the meso-diaminopimelic acid direct type and contained putrescine residues.

RIBOTYPING Automated ribotyping has been used for characterization of 13 *Megasphaera cerevisiae* strains using three restriction enzymes *Eco*RI, *Pst*I and *Pvu*II (Suihko and Haikara, 2001). Using a combination of the enzymes, the strains could be divided into seven ribotypes, of which one probably represented a novel species within the genus.

Taxonomic Differentation of *Zymophilus*

The Gram-negative, anaerobic bacteria isolated from pitching yeast were preliminarily classified as *Pectinatus* (Back, 1981; Haikara, 1989). The taxonomic rearrangement of anaerobic, Gram-negative, rod-shaped bacteria from breweries revealed a new genus comprising the two species *Zymophilus raffinosivorans* and *Z. paucivorans* and a new species *Selenomonas lacticifex* (Schleifer et al., 1990). The G+C contents of DNAs of *Zymophilus* and *Pectinatus* spp. were similar (i.e., 38–41 mol%), different from those of *Selenomonas* and *Megasphaera* spp. (Table 1). The DNA/DNA hybridization studies showed that *Zymophilus* species formed a distinct genospecies compared to *Pectinatus* and *Selenomonas* spp. *Zymophilus paucivorans* strains exhibited high similarity values with each other (>75%), and also a distinct relationship (44–48%) to *Z. raffinosivorans* strains (Schleifer et al., 1990).

CELL WALL The cell wall of *Zymophilus* spp. as well as that of *Pectinatus* and *Selenomonas* species contained the directly cross-linked meso-diaminopimelic acid peptidoglycan type (Schleifer et al., 1990). In addition, the α-carboxyl group of D-glutamic acid was substituted predominantly by cadaverine, and in some strains a minor amount of cadaverine was replaced by putrescine. Such a peptidoglycan type containing a diamine-substituted glutamic acid has previously been found in strains of *M. cerevisiae* (Engelmann and Weiss, 1985), *Veillonella* species

and *Centipeda periodontii*, indicating the relationship of *Zymophilus* spp. to the subdivision of species with Gram-negative cell walls within the phylum of Gram-positive eubacteria. Lipid F was also found as a characteristic cellular compound (Schleifer et al., 1990).

RIBOTYPING *Zymophilus raffinosivorans* and *Z. paucivorans* have been characterized by digestion with the restriction enzyme *Eco*RI (Motoyama et al., 1998; Suihko and Haikara, 2001). These species were completely different from those of the genus *Pectinatus*, indicating that the patterns of fragments were species-specific.

Table 2 summarizes the characteristics of Gram-negative, anaerobic genera isolated from brewing processes. The physiological differentiation can be based on the acetoin production of *Pectinatus*, lactic acid production of *Selenomonas lacticifex* or on the coccoid cell morphology of *Megasphaera*. For differentation on the species level, the utilization of carbohydrates must be determined (Table 2).

Habitat

Pectinatus and *Megasphaera* constitute an important group of spoilage bacteria of unpasteurized packaged beer. *Pectinatus* contaminations have occurred in most European countries and in the United States. *Megasphaera cerevisiae* is apparently less widespread and has been reported only in Germany, Australia and Finland. The natural environment of anaerobic beer spoilage organisms and the source of contaminations are not known. Most of the strains described and characterized (to date) have been isolated almost exclusively from spoiled beer. The occurrence of *Pectinatus* and *Megasphaera* in pitching yeast has been reported (Back, 1981; Seidel, 1985; Haikara, 1989). However, some of these isolates have later been reclassified as a new *Selenomonas lacticifex* species (Schleifer et al., 1990). *Pectinatus* has also sporadically been found in lubrication oil mixed with beer, in drainage and water pipe systems, in the air of the filling hall, in the filling machine, on the floor of the filling hall, in condensed water on the ceiling, in chain lubricants, and in steeping water of malt before milling (Back et al., 1988; Dürr, 1983; Haukeli, 1980; Lee et al., 1980; Soberka et al., 1986). The *Pectinatus* findings in Finland (Haikara, 1991) also have concentrated in the filling hall, indicating water is a most likely source of contamination. Moreover, it is obvious that *Pectinatus*, despite its anaerobic nature, can survive in aerosols and be transferred via the air into beer. The detection of *Pectinatus* in air near unclear bottles

Table 2. Differential characteristics of anaerobic Gram-negative bacteria isolated from spoiled beer and from pitching yeast.

and close to the bottling machine in the filling hall indicates the possibility that air may be a contamination source (Dürr, 1983; A. Haikara, unpublished observations; Hakalehto, 2000). Hakalehto (2000) clearly demonstrated the general presence of *Pectinatus* in different parts of the brewery and considered his findings as a proof that the contaminating strains were in fact permanent inhabitants rather than occasional invaders of the brewery and that they find niches in the factory where they can survive.

Rather high frequencies of contaminations caused by *Pectinatus* and *Megasphaera* were reported in the 1980s (Haikara, 1991). Since then at least the reported cases have declined although the "anaerobic" filling technique and the low oxygen content of beer increasingly favor the growth of anaerobic beer-spoilage organisms. It has been somewhat controversial whether *Pectinatus* has resided in breweries over longer periods of time, or is a recent arrival with raw material. For example, on the basis of the occurrence D-fucose in the O-specific chains of *Pectinatus* lipopolysaccharides, it was speculated (Helander et al., 1992) that *Pectinatus* originated from plant material, inasmuch as 6-deoxy D-hexoses are uncommon in nature except in plant pathogenic Gram-negative bacteria. The O-specific sugar in *P. frisingensis*, however, later proved to be 6-deoxyaltrose in the L configuration (Senchenkova et al., 1995), showing that the presence of D-6-deoxyhexoses is not an obligatory component within the genus.

The strictly anaerobic *Zymophilus raffinosivorans* and *Z. paucivorans* are very rare

brewery contaminants and hitherto have been isolated only in Germany from pitching yeast and brewery waste (Seidel-Rüfer, 1990; Schleifer et al., 1990). *Zymophilus raffinosivorans* is considered a potential spoilage organism, because it can grow in beer if the pH is high (i.e., around 5; Seidel-Rüfer, 1990). *Zymophilus paucivorans* is regarded as harmless owing to its inability to grow below pH 6.

Growth of *Pectinatus* and *Megasphaera* in Beer

It has been observed in practice and in laboratory tests that beer with low alcohol content (<2.25% w/v) is more prone to *Pectinatus*, and especially to *Megasphaera*, contamination than beer with higher alcohol content (Haikara, 1984; Haikara and Lounatmaa, 1987). The rate of spoilage is inversely dependent on the alcohol content of beer. The growth of *Megasphaera* is already restricted in commercial beer with an alcohol content of 3.5% (w/v). *Pectinatus* bacteria are more alcohol-tolerant, growing rather well in beer with higher alcohol contents (3.7–4.4% w/v), although the growth is slower than in low-alcohol beer. As reported earlier, *Pectinatus* does not grow in strong beer with an alcohol content exceeding 5.2% (w/v; Haikara et al., 1981b; Haukeli, 1980; Kirchner et al., 1980; Seidel et al., 1979).

The low pH of beer is one of most important characteristics affecting the growth of microorganisms in beer. The higher the pH of beer, the

more susceptible it is to *Megasphaera* contamination. *Pectinatus* is very acid-tolerant. A pH value of 4.1 is required for retardation of its growth, whereas the normal beer pH of 4.5 already restricts the growth of *Megasphaera* (Haikara, 1984; Haikara and Lounatmaa, 1987). In German Alt beer (pH 4.0), the growth of *Megasphaera* is prevented, but *Pectinatus* can still grow slowly in it (Kirchner et al., 1980; Seidel et al., 1979).

Hop bitter substances generally restrict the growth of microorganisms in beer. However, both *Pectinatus* and *Megasphaera* are rather tolerant of hops, inasmuch as growth occurs in beer with bitterness in the range of 33–38 European Brewery Convention units (Back, 1981; Kirchner et al., 1980; Seidel et al., 1979). The growth of *Pectinatus* and *Megasphaera* bacteria in beer is dependent on the combined effects of several factors, the oxygen content of beer being the most decisive. The dissolved oxygen content as well as the volume of air in the headspace has decreased considerably in recent years due to advances in filling technology. At present an air volume of 1 ml or less in the headspace is easily achievable, as is an oxygen content of as little as 0.3 mg/liter (Seidel et al., 1979).

It has been reported that treatment at 58–60°C for one minute, which is less than normal pasteurization treatment, is sufficient to kill *Pectinatus* bacteria (Lee et al., 1981; Haukeli, 1980). Watier et al. (1995) studied the heat resistance of *Pectinatus* spp. in wort and culture medium, confirming the low D–60 values (a measurement of heat resistance at 60°C) for *Pectinatus* in wort. Some differences existed between species depending on the pH and the medium used.

The elimination of contaminations caused by anaerobic beer spoilers requires adequate cleaning, disinfection and sterilization of equipment susceptible to contamination. Lee et al. (1981) reported that iodine and chlorine were effective disinfectants for the control of *Pectinatus* spp. In our experiments, in which different disinfectants were tested, peracetic acid (0.75%, 1 min) and formaldehyde (0.3%, 1 min) were most efficient (Haikara, 1984). Disinfectants with iodine as the active compound proved to be ineffective. *Megasphaera* was killed most easily with oxidizing agents, iodophor having no effect (Haikara, 1991). Quaternary ammonium compound (0.2%) killed *Megasphaera* cells in one minute.

The detection of *Pectinatus* in the air of the handling area of dirty bottles has been proposed as one simple way to eliminate at least this source of contamination: treatment of dirty bottles and cases with a disinfectant before their entry to the filling hall could diminish the risk of airborne contamination of beer (Anonymous, 1988).

Isolation

Cultivation and Detection of *Pectinatus*

Many agar media and broths can be used for cultivation and isolation of *Pectinatus* strains. The most commonly used are de Man-Rogosa-Sharpe (MRS) lactobacilli broth or agar, or modified MRS medium (Schleifer et al., 1990). Peptone-yeast extract-fructose (PYF) medium (Engelmann and Weiss, 1985) intended for cultivation of *Megasphaera* species has also been used for *Pectinatus* (Satokari et al., 1997; Satokari et al., 1998; Juvonen et al., 1999). A selective medium for the isolation and differentation of *Pectinatus* spp. and *Megasphaera cerevisiae* from other brewery organisms, so-called "Selective Medium *Megasphaera*, *Pectinatus*" (SMMP) medium, was developed by Lee (1994). This new medium should replace the earlier lactate-lead acetate (LL)-medium especially designed for selective cultivation and isolation of *Pectinatus* spp. (Lee et al., 1981). The SMMP medium is beer-based and supplemented with reducing agents, various nutrients, 1% lactate as the sole carbon source, 20 ppm actidione (cycloheximide) to inhibit yeasts and 5 ppm crystal violet and 25 ppm sodium fusidate to inhibit Gram-positive bacteria. Enterobacteria are suppressed by alcohol and by hop compounds present in beer, and hence appropriate levels of ethanol must be incorporated into SMMP when nonalcoholic beer is assayed (Lee, 1994).

SMMP (Selective Medium *Megasphaera*, *Pectinatus*)

A concentrated basal medium with

Yeast extract	75 g
Bacto-peptone	75 g
DL-Lactic acid, sodium salt (60% syrup)	75 ml
Sodium thioglycollate	0.75 g
L-Cysteine HCl	0.75 g
$KH_2PO_4 \cdot 3H_2O$	7.5 g
KH_2PO_4	7.5 g
NaCl	7.5 g
$(NH_4)_2 HPO_4$	7.5 g
$NaC_2H_3O_2 \cdot 3H_2O$	7.5 g
H_2O	728.5 ml

B1 selective stock solution

Sodium fusidate[a]	0.75 g
Cycloheximide[b]	0.60 g
Crystal violet[a]	0.075–0.15 g
Absolute ethanol	100 ml

[a] Sigma or equivalent.
[b] Upjohn or equivalent.
From Lee (1994).

The American Society of Brewing Chemists recommends addition of 20-ml aliquots of basal medium and 0.5 ml of selective stock-solution to 130 ml of beer followed by incubation for 14 days at 28–30°C (Anonymous, 1997; 1998). The final concentration of crystal violet in the medium could be reduced from 5.0 to 2.5 ppm without affecting the results (Haikara, A., unpublished observations). In the original paper a freshly prepared mixture of selective agents was recommended (Lee, 1994). However, a storage time of as long as 93 days at 6°C did not abolish the selectivity of SMMP-medium (Haikara, A., unpublished observations).

More important than the media used for cultivation of *Pectinatus* and *Megasphaera* species is the maintenance of strictly anaerobic conditions for cultivation and incubation. The anaerobic glove box and the Gas Pak system provide optimum growth conditions for *Pectinatus* bacteria (Back et al., 1979; Haikara et al., 1981a; Haikara et al., 1981b; Kirchner et al., 1980; Lee et al., 1978). Using pre-reduced media and special reducing agents can enhance growth (Holdeman et al., 1977). Cultivation without an anaerobic atmosphere in broth with a minimum headspace is possible provided that the inoculum is heavy (2%) and that the oxygen is removed by boiling before use (Haikara et al., 1981a; Lee, 1984).

In quality control of beer, the presence of microorganisms is conventionally detected using membrane filtration and anaerobic incubation on an appropriate medium. Because *Pectinatus* species are sensitive to oxygen, this method is unsuitable for the detection of *Pectinatus* in beer (Haikara, 1985b). Because an anaerobic cabinet is not generally available in brewery laboratories, forcing tests or enrichment are the practical methods available in routine control of beer (European Brewery Convention, 1992a; 1992b). In forcing tests, the development of turbidity is followed in filled, closed beer bottles incubated at 30°C for 6 weeks. In the enrichment method, 15–20 ml of sterilized, concentrated MRS broth (72 g/liter) supplemented with fructose (10 g/liter) is added to the headspace of the bottle immediately after filling and capping. The bottle is reclosed with a sterile cap and incubated at 30°C for 4 weeks. After development of turbidity, the presence of *Pectinatus* and *Megasphaera* is examined microscopically. They are identified morphologically and by smell. In practice, an incubation time of 2–3 weeks is usually needed for *Pectinatus* growth, and 3–4 weeks for *Megasphaera*.

Shortening of the forcing time has been achieved by direct staining of cells on the membrane after visualization with the immunofluorescence technique or the direct epifluorescent filter technique (DEFT) with acridine orange (Haikara, 1985a; Haikara, 1985b). Direct staining has revealed contaminations one to four days before the appearance of turbidity.

Because the metabolic profiles of *Pectinatus* are distinctive (see Identification and *Megasphaera* Identification), gas chromatography also has been tested as a detection method (Haikara et al., 1981a; Haikara et al., 1981b). Detectable amounts of propionic acid were formed without visible growth of Pectinatus, one day before the turbidity appeared. Correspondingly, *n*-butyric or *n*-valeric acid produced by *Megasphaera* could be detected one day before the beer became turbid.

Winnewisser and Donhauser (1987) developed an indirect enzymatic immunotest for detection of *Pectinatus* in beer after membrane filtration. The detection limit of this assay was 50 cells/ml beer. Sample enrichment is necessary to reach the required cell density because normally there are only a few cells in one bottle of beer.

Takahashi et al. (1999) applied a new automatic MicroStar RMDS system, based on ATP bioluminescence, for rapid quantitative detection of brewery contaminants. For slow-growing *Pectinatus* bacteria, a 32-h cultivation was insufficient, but by using a high sensitivity luminous reagent for measurement, some improvement was achieved.

Cultivation and Detection of *Megasphaera*

Owing to the inability of *Megasphaera* sp. to utilize glucose, replacement of glucose with fructose in the peptone-yeast extract medium is necessary for maximal growth of *Megasphaera* species (Engelmann and Weiss, 1985). A simple PYF broth (1% peptone, 1% yeast extract, 2% fructose) also has been successfully utilized for cultivation of *Megasphaera* species (Haikara and Lounatmaa, 1987). When using SMMP medium for selective cultivation of *Megasphaera*, the change of the medium color from purple to yellow indicates the presence of *Megasphaera* bacteria (Anonymous, 1988). Because *M. cerevisiae* is a strict anaerobe, the anaerobic cultivation conditions recommended for *Pectinatus* are also valid for *Megasphaera*. Immunofluorescence, DEFT and gas chromatography have also been used as detection methods of *Megasphaera* (Haikara, 1985a; Haikara, 1985b).

Cultivation and Detection of *Zymophilus*

Strictly anaerobic conditions are required for the detection and cultivation of *Zymophilus* species. Modified MRS and MRS medium at 30°C have been used (Ziola et al., 1999; Schleifer et al., 1990). Only 14 days in a refrigerator is the maximum time for the storage of working cultures

owing to the rapid death of cells in four weeks (Seidel-Rüfer, 1990).

Ziola et al. (1999) prepared a panel of monoclonal antibodies (Mabs) for rapid detection and identification of beer-spoilage anaerobic bacteria including *Zymophilus paucivorans* and *Z. raffinosivorans*. The panel contained Mabs that were able to recognize four distinct sites (epitopes) on the bacterial peptidoglycan; hence, to facilitate antibody binding, the bacterial outer membrane must first be removed.

Identification

Pectinatus

MORPHOLOGY The most distinctive feature of *Pectinatus* species is the comb-like flagellation on only one side of the cell (Fig. 1). The number of flagella per cell depends on the cell size and condition, but is generally 1-23 (Lee, 1984). The cells of *P. cerevisiiphilus* and *P. frisingensis* are Gram-negative, slightly curved rods with rounded ends, 0.4 to 0.9 μm in diameter and 2 to 30 μm or more in length (Back et al., 1979; Haikara et al., 1981b; Lee et al., 1978; Schleifer et al., 1990). They occur singly, in pairs and only rarely in short chains. In old cultures, very elongated cells with a helical shape may be found (Fig. 2) and round cell forms are also observed. The cells are usually motile. The active, young cells form an "X" shape during movement, whereas old cells have characteristically slow snakelike movements (Lee et al., 1978). In beer the cells are thin and have a heterogeneous appearance (Seidel et al., 1979).

Colonies of *P. cerevisiiphilus* and *P. frisingensis* are circular, entire, beige to white, glistening and opaque (Haikara et al., 1981b; Schleifer et al., 1990).

ELECTRON MICROSCOPY The unique comb-like flagellar arrangement of *P. cerevisiiphilus* observed by Lee et al. (1978) using scanning electron microscopy was confirmed by other workers in negatively stained preparations (Back et al., 1979; Haikara et al., 1981b; Kirchner et al., 1980). The cell envelope structure seen in such sections revealed a multilayered cell wall typical of Gram-negative bacteria (Lee et al., 1978). The peptidoglycan layer of *Pectinatus* is very thick (30 nm), almost filling the periplasmic space of the cell envelope (Haikara et al., 1981a, Haikara et al., 1981b). The freeze-fracture technique has also been used to investigate *Pectinatus* strains (Haikara et al., 1981a; Haikara et al., 1981b). These studies have demonstrated that the cell envelope structure in different *Pectinatus* strains is similar (Haikara et al., 1981a). The

Fig. 2. Dark-field micrograph of *Pectinatus frisingensis* ATCC 33332.

thick peptidoglycan layer and the invaginations of the cytoplasmic membrane (mesosomes) are typical features of Gram-positive bacteria, whereas the outer membrane is typical of Gram-negative bacteria. The outer membrane of *Pectinatus*, however, is exceptional since it lacks permeability barrier function normally assigned to the outer membrane of Gram-negative (e.g., the enteric) bacteria (see Physiology).

CHROMATOGRAPHIC IDENTIFICATION   *Pectinatus* species are the only bacteria known to produce large quantities of propionic acid in beer, and hence gas chromatography has proved to be a useful tool for identification purposes (Back et al., 1979; Haikara et al., 1981b; Lee et al., 1978; Lee et al., 1980; Schisler et al., 1979; Membré and Tholozan, 1994; Foster and Beckler Andersen, 1999). The production of acetic acid in broth media and in beer further confirms the presence of *Pectinatus* (Foster and Beckler Andersen, 1999). The production of high levels of hydrogen sulfide (H_2S) by *Pectinatus* can also be used for identification purposes (Haikara et al., 1981a). In lager breweries, no other contaminants are able to produce H_2S. In British ale, the genus *Zymomonas* is known as an H_2S-producing spoilage organism. The simultaneous production of acetaldehyde by this bacterium, however, results in an odor of rotten apples in the ale. This is easily distinguishable, even without any instruments, from the odor of rotten eggs caused by the growth of *Pectinatus* in beer.

SEROLOGICAL CHARACTERISTICS Initial immunological investigation of the genus *Pectinatus* involving the use of polyclonal antibodies in gel immunodiffusion and immunoelectrophoresis tests revealed three serologically different groups (I, II and III) within the genus *Pectinatus* (Haikara, 1983; Haikara et al., 1981a; Haikara et al., 1981b). Groups I and III were more closely related to each other than to the more distant group II. The division of *Pectinatus* strains into two groups (I and II) was supported by differences in the cell surface protein patterns and by immunoblot analysis using surface components extracted with mild hydrochloric acid; the same antisera as were used in immunodiffusion (Haikara, 1983; Hakalehto et al., 1984; Hakalehto and Finne, 1990). Later the immunogroups I and II turned out to correspond to the designated two species of the genus, namely *P. frisingensis* and *P. cerevisiiphilus* (Schleifer et al., 1990). Previously, DNA/DNA hybridization studies had also revealed two distinct similarity groups among *Pectinatus* strains (Haikara, 1989), supporting the division of the genus *Pectinatus* into two species (see Physiology).

Gares et al. (1993) and Ziola et al. (1999) studied the reactivity of monoclonal antibodies (Mabs) with disrupted and intact *Pectinatus cerevisiiphilus* cells to detect and identify *Pectinatus* contaminations. Some Mabs reacted only with surface antigens from intact *P. cerevisiiphilus* cells and could be used in a membrane filter-based fluoroimmunoassay (MF-FIA) for detection and identification of *P. cerevisiiphilus* in contaminated beer samples (Gares et al., 1993). Using this assay, *Pectinatus* cells could be detected at concentrations as low as 2 to 4 cells in 10 ml, within less than 3 h, by trapping the bacteria on a black filter membrane and marking them with fluorescein-conjugated anti-mouse secondary antibodies. These secondary antibodies attached to the primary monoclonal antibodies that were already bound to the bacteria and thereby made them visible under a fluorescence microscope. Most of the Mabs, however, reacted only with cells from which the outer membrane had been removed, suggesting the involvement of the peptidoglycan (PG) layer in binding (Ziola et al., 1999). Because the Mabs also bound to disrupted *P. frisingensis*, *Selenomonas lacticifex*, *Zymophilus paucivorans*, *Z. raffinosivorans* and *Megasphaera cerevisiae* cells and not with other species of Gram-negative bacteria, they can be used to rapidly detect a range of anaerobic Gram-negative beer spoilage bacteria, provided that the bacterial outer membrane is first removed to allow antibody binding.

To immunologically characterize *Pectinatus* strains and to provide means of for their detection, subgrouping and identification, Hakalehto and Finne (1990) and Hakalehto et al. (1997) prepared antibodies against whole-cell preparation, flagellin protein and the N-terminal flagellar peptide of *Pectinatus* strains. An immunoluminometric analysis including a mixture of anti-peptide antibodies against antigenic sequences from *Pectinatus* (synthetic peptides) and a serum against *P. frisingensis* was developed (Hakalehto, 2000).

MOLECULAR BIOLOGICAL METHODS The polymerase chain reaction (PCR) has recently been applied for the identification and detection of *Pectinatus* species (Satokari et al., 1997; Satokari et al., 1998; Juvonen et al., 1999; Sakamoto et al., 1997; Motoyama and Ogata, 2000a). Sakamoto et al. (1997) designed highly species-specific primers for *P. frisingensis*, *P. cerevisiiphilus* and *M. cerevisiae* based on 16S rRNA sequences. The combined use of these primers and the universal primers in a single reaction guaranteed the reliability of the PCR results. Satokari et al. (1997) and Satokari et al. (1998) designed *Pectinatus* and *M. cerevisiae*-specific PCR primers from the 16S rRNA gene sequences to develop a rapid

and sensitive detection method for use in brewery quality control. Later Juvonen et al. (1999) improved the sample treatment and the sensitivity of the PCR assay by pre-enrichment. The enrichment ensured that the cells detected are still alive, thus reducing the risk of false positive results. Low levels of *Pectinatus* spp. and *M. cerevisiae* were detected after 2–4 days of pre-enrichment, depending on the strain and the alcohol content of the beer. After the pre-enrichment, the PCR analysis took less than 8 hours.

Motoyama and Ogata (2000a) constructed PCR primers from the spacer region between 16S rDNA and the 23S rDNA genes, developing a rapid and sensitive method for the detection of *P. cerevisiiphilus* and *P. frisingensis*. This method allowed the discrimination of these two closely related species because the homology of the 16S-23S rDNA intergenic spacer regions was relatively low compared to that of the 16S rDNAs (see Phylogeny; Motoyama and Ogata, 2000b).

Megasphaera

MORPHOLOGY Megasphaera cerevisiae is a Gram-negative coccus (Figs. 3 and 4). The spherical or slightly oval cells, 1.3 to 1.6 μm in diameter, occur singly or in short chains (Engelmann and Weiss, 1985). In fixed or stained preparations the cell diameter is 1.0–1.2 μm (Haikara and Lounatmaa, 1987). Cell size is one differential characteristic between the brewery species and *M. elsdenii*. In wet mounts, the diameter of *M. elsdenii* is 2.4–2.6 μm and in fixed preparations 1.2–1.9 μm, in accordance with its Latin name: big sphere (Rogosa, 1984). The ultrastructure of the cell surface of the *Megasphaera* strains isolated from beer

and of *M. elsdenii* has been reported to be very uniform (Haikara and Lounatmaa, 1987). *Megasphaera cerevisiae* forms whitish, smooth, opaque, flat and shiny colonies, 2–5 μm in diameter (Engelmann and Weiss, 1985; Weiss et al., 1979).

CHROMATOGRAPHIC IDENTIFICATION The distinctive metabolic profile of *Megasphaera cerevisiae* (Haikara, 1985a; Weiss et al., 1979; Foster and Beckler Andersen, 1999) provides a useful tool for its identification. This profile includes propionic, isobutyric, isovaleric, valeric and caproic acids. The gas chromatographic detection of these acids in brewery samples can be regarded as proof of the presence of *M. cerevisiae* (Foster and Beckler Andersen, 1999). The identification can be complemented with detection of H_2S produced by *Megasphaera*.

SEROLOGICAL CHARACTERISTICS Hakalehto (2000) produced anti-peptide antibodies against *Megasphaera* surface protein (40–50 kDa) and found crossreactivity in the immunoblots between *Pectinatus* and *Megasphaera* protein bands. Similarly the antibodies produced with the N-terminal peptide of the *Pectinatus* 16-kDa surface protein exhibited specific activity against the *Pectinatus* 51-kDa surface protein band from immunoblots and against the *Megasphaera* surface protein band of slightly smaller molecular weight.

Using *P. cerevisiiphilus* cells Ziola et al. (1999) succeeded in producing peptidoglycan (PG)-specific Mabs that reacted not only with *Pectinatus*, *Zymophilus* and *Selenomonas* species, but also with *Megasphaera cerevisiae*. Although the
Fig. 3. Electron micrograph of *Megasphaera cerevisiae* VTT E-84195.
Fig. 4. Dark-field micrograph of *Megasphaera cerevisiae* VTT E-84195.

binding of PG epitopes of *M. cerevisiae* was weak, the PG Mabs also could potentially be used for rapid detection of Megasphaera. For selective detection and identification of *Megasphaera cerevisiae*, bacterial surface-reactive Mabs corresponding to the three different serogroups were produced and used in a fluoro-immunoassay format (Ziola et al., 2000).

MOLECULAR BIOLOGICAL METHODS PCR-based methods have recently been developed for the detection and identification of *M. cerevisiae* (Satokari et al., 1998; Sakamoto et al., 1997; Juvonen et al., 1999). Satokari et al. (1998) developed a method in which amplified PCR products were analyzed by the colorimetric microplate hybridization method. A biotinylated PCR product was captured by streptavidin and hybridized with a digoxigenin-labelled oligonucleotide probe. In the final step an enzyme-linked antibody and a colorimetric reaction were utilized.

Juvonen et al. (1999) combined a pre-enrichment with the PCR assay and managed to detect low levels of *M. cerevisiae* cells (after 2–3 days of enrichment) by gel electrophoretic analysis of the PCR products. The universal primers were used as an internal positive control in the PCR method, based on 16S rDNA sequences, and applied to species-specific detection of *M. cerevisiae* (Sakamoto et al., 1997).

Zymophilus

MORPHOLOGY Schleifer et al. (1990) described *Zymophilus raffinosivorans* as straight to slightly curved, motile, Gram-negative rods (0.7 to 0.9 by 3 to 15 μm in size) with rounded ends, occurring predominantly singly and sometimes in pairs or short chains. Colonies on modified MRS agar medium are circular, smooth, opaque, slightly yellow, and 1 to 2 μm in diameter after 3 days at 30°C.

Zymophilus paucivorans cells are motile, curved, helical or crescent-shaped, Gram-negative rods (0.8 to 1.0 by 5 to 30 μm) with rounded ends (Schleifer et al., 1990). They occur singly or in pairs or short chains. Colonies on modified MRS agar medium are circular, smooth, slightly yellow and 1 to 2 μm in diameter after 3 days at 30°C.

Preservation

Working cultures of *Pectinatus*, *Megasphaera* and *Zymophilus* can be maintained by subculturing (30°C, 2–3 days) at least every two weeks in PYF broth (0.5% peptone, 0.5% tryptone, 1% yeast extract, 0.5% fructose, 0.2% Na₂HPO₄,

0.1% Tween 80, and 0.05% cysteine hydrochloride added as a reducing agent). The *Selenomonas* and *Zymophilus* strains isolated from pitching yeast lose their viability rapidly (Seidel-Rüfer, 1990; Haikara, 1991), and subculturing every week is necessary. After incubation, the cultures are stored at 4°C in anaerobic jars. The working cultures can also be maintained in 5% dimethyl sulfoxide in plastic screw-cap ampoules frozen at −70°C.

For long-term preservation conventional freeze-drying methods using 20% skim milk as protective agent as well as freezing in drinking straws in a −150°C deep freezer or in liquid nitrogen at −196°C using 5% dimethyl sulfoxide as protective agent have been used. The polypropylene straws are packed after filling (0.1 ml) into 2-ml plastic screw-cap ampoules (e.g., Nunc) and placed directly into liquid nitrogen (Suihko and Haikara, 1990).

Physiology

Physiological and Biochemical Properties of *Pectinatus*

Pectinatus species are catalase- and cytochrome oxidase-negative, and do not produce indole, liquify gelatin, reduce nitrate, or hydrolyze arginine. The Voges-Proskauer test is positive for all strains (Back et al., 1979; Haikara et al., 1981b; Kirchner et al., 1980; Lee et al., 1978). Only the urease test has given variable results for different strains (Back et al., 1979; Haikara et al., 1981b).

Pectinatus species grow at temperatures between 15 and 40°C, the optimum being 30 to 32°C (Back et al., 1979; Haikara et al., 1981b; Kirchner et al., 1980; Lee et al., 1978). Chowdhury et al. (1995) studied the effect of temperature on their survival and oxygen resistance. The survival was better at lower temperatures (8°C, 15°C) than at 32°C. Temperature also inversely influenced the oxygen resistance of *Pectinatus*. The time of decimal reduction (an inactivation kinetic parameter used to indicate rate of microbial reduction) decreased by 6.7 fold when the temperature decreased from 32°C to 8°C. The oxygen resistance of *P. frisingensis* was higher than that of *P. cerevisiiphilus*, which has also previously been observed (Haikara, 1985b). In wort, dissolved oxygen levels below 0.96 mg/liter made the growth of *Pectinatus* possible (Chowdhury et al., 1995).

Pectinatus strains grow well in the pH range 4.5–8.5 (Back et al., 1979; Haikara et al., 1981b), the optimum pH being between 6.0 and 7.0 (Kirchner et al., 1980; Takahashi, 1983). However, rather good growth occurs even in the pH

range 4.0 to 4.5 (Kirchner et al., 1980). The acid tolerance of *Pectinatus* was also verified in growth tests in beer (Haikara, 1984). The normal pH of Finnish beer (average 4.4) did not restrict the growth of *Pectinatus* sp. Some retardation of growth was detected at pH 4.1. In German Alt beer (pH 4.0), the growth of *Pectinatus* was considerably reduced but still not totally prevented (Kirchner et al., 1980; Seidel et al., 1979). In the German beer type Berliner Weisse, with a pH of 3.1, no growth occurred (Kirchner et al., 1980).

A number of studies on *Pectinatus* growth in the culture medium as a function of temperature, pH and ethanol concentration have been performed (Tholozan et al., 1996; Tholozan et al., 1997; Chihib and Tholozan, 1999a; Chihib et al., 1999b) including modeling of growth and metabolite production (Membré and Tholozan, 1994; Watier et al., 1996b). In general, the parameters derive from those encountered in beer production, including rapid temperature changes in pasteurization and cooling before bottling. Whereas ethanol concentrations of 1.7 M (8%) totally inhibit the growth of both *Pectinatus* species (Tholozan et al., 1996; Watier et al., 1996b), *P. frisingensis* appears to be less sensitive than *P. cerevisiiphilus*, which does not tolerate ethanol at 1.3 M (Tholozan et al., 1996; Tholozan et al., 1997). Similarly, *P. frisingensis* copes better with low pH and is able to grow over a wider pH range than *P. cerevisiiphilus*; for the latter, pH 6.2 is optimal for growth and biomass production, whereas for the former, pH of approximately 4.9 is optimal for growth and biomass production in glucose concentrations below 20 mM (Tholozan et al., 1997). In accord with its higher acid tolerance, *P. frisingensis* is able to maintain a higher intracellular pH than the external pH even at pH 4.5 (Chihib and Tholozan, 1999a). A cooling treatment from 30°C to 2°C does disturb the cellular homeostasis of P. frisingensis but this effect is only temporary, as the bacterium is able to restore homeostasis under warm conditions and in the presence of a carbon source (Chihib and Tholozan, 1999a). The physiological characteristics of *P. frisingensis* as compared to *P. cerevisiiphilus* may suggest that the former species is the prevailing one in beer spoilage.

Although the structure of *Pectinatus* lipid A, with a large degree of phosphate substitution by 4-amino-4-deoxyarabinose, would suggest that these bacteria are resistant to cationic agents such as polymyxin B, the opposite turns out to be true (Helander et al., 1994). This surprising result is explained by findings indicating that the outer membrane of *Pectinatus* does not form an effective barrier: the above study also demonstrated a high sensitivity of *Pectinatus* strains to vancomycin and bacitracin, which are rather large molecules (M_r, 1449 and 1411, respectively)

unable to penetrate a normal outer membrane in most bacteria (Vaara, 1993). Furthermore, *P. frisingensis* was shown to be sensitive to nisin, which is a cationic peptide acting lethally on the bacterial cytoplasmic membrane, but is unable to penetrate an intact outer membrane (Chihib et al., 1999b). Gram-negative bacteria are normally insensitive to nisin action (Helander et al., 1997). Supported by electron microscopic observations that Pectinatus strains have an abnormally wrinkled outer membrane (Haikara et al., 1981b; Lee et al., 1978), the conclusion has been drawn that the outer membrane of *Pectinatus* has cracks that permit the entry of various external compounds.

Metabolism

Clear differences exist in the utilization of carbon sources by the two *Pectinatus* species (Schleifer et al., 1990; Haikara, 1991; Table 2). In contrast to other brewery contaminants, *Pectinatus* strains are incapable of utilizing maltose, the main carbohydrate of wort. On the other hand they can utilize lactate. Thus the presence of lactic acid bacteria in the brewery environment can facilitate the growth of *Pectinatus*.

The main metabolic products of *Pectinatus* species from glucose are propionic, acetic, succinic and lactic acids and acetoin (Back et al., 1979; Haikara et al., 1981b; Lee et al., 1978; Tholozan et al., 1994; Table 1). The relative amounts of metabolites are dependent on the substrate utilized by *Pectinatus* (Back et al., 1979; Lee et al., 1978). However, no differences in this respect were found between different strains (Haikara et al., 1981b). The most abundant acid produced by *Pectinatus* is propionic acid. The amount found in contaminated beer is rather high, often more than 1,000 mg/liter (Haikara et al., 1981a; Takahashi, 1983).

The organic acids produced by *Pectinatus* and the low pH were obviously the main reasons for the growth inhibition and alcohol production of *Saccharomyces cerevisiae* in mixed fermentations above 15°C (Chowdhury et al., 1997). No effect was found in typical lager beer fermentations around 8–15°C.

Haikara et al. (Haikara et al., 1981a; Haikara et al., 1981b) and Tholozan et al. (1994) studied the mechanism of propionic acid synthesis by *Pectinatus*. *Pectinatus* bacteria use the same pathway for production of propionic acid as do propionibacteria. In this pathway, succinate oxidoreductase catalyzes the reduction of fumarate to succinate (Hettinga and Reinhold, 1972). Malonate is a specific competitive inhibitor of this enzyme and can thus inhibit the production of propionic acid, leading to a corresponding increase in acetic acid production. This was shown to occur in different *Pectinatus* strains and

also in *Propionibacterium* species (Haikara et al., 1981a; Haikara et al., 1981b). This observation was taxonomically significant because *Bacteroides* species are known to use the acrylate pathway for propionate synthesis (Wallnöfer and Baldwin, 1967). Later Tholozan et al. (1994) confirmed propionate production by *P. frisingensis* through the succinate pathway by measuring key enzyme activities and by studying the utilization of specially labeled metabolic precursors. The authors also proposed a tentative metabolic pathway to the main fermentation products of *P. frisingensis*.

A very specific feature of the metabolism of *Pectinatus* sp. is the production of organic sulfur compounds (Haikara et al., 1981a). In addition to H_2S detected by Lee et al. (1980), production of methyl mercaptan and dimethyl trisulfide has been observed. Gas chromatographic analysis did not reveal the formation of dimethyl disulfide or thiolacetate.

Physiological and Biochemical Properties of *Megasphaera*

Megasphaera elsdenii has been used as a reference species in the physiological and biochemical tests of the beer isolate (Weiss et al., 1979; Haikara and Lounatmaa, 1987). The optimum temperature for *Megasphaera* beer isolates is 30–37°C and for *M. elsdenii* 37–42°C. *Megasphaera elsdenii* does not grow at room temperature but the brewery isolates can grow even at 15°C. A slightly lower optimum temperature of 28°C has been reported for the type strain *M. cerevisiae* (Engelmann and Weiss, 1985).

Megasphaera sp. is more sensitive to low pH than *Pectinatus* sp., especially in beer. Increase in the pH of beer from 4.1 to 4.7 was found to accelerate the growth of *Megasphaera* sp. (Haikara and Lounatmaa, 1987). No growth occurs at pH 4.1. Seidel et al. (1979) also reported the growth of *Megasphaera* sp. in beer of pH from 4.38 to 4.57, but not at pH 4.0.

In addition to low pH, alcohol is the most important factor inhibiting the growth of *Megasphaera* in beer. Very small amounts of ethanol retard the growth of *Megasphaera* sp. (Haikara and Lounatmaa, 1987). The dependence of the rate of spoilage on the alcohol content was also demonstrated in experiments in which growth of *Megasphaera* sp. was monitored in commercial beers with different alcohol contents (Haikara, 1991). Growth did not occur in beer with an alcohol content of 4.3% w/v. Correspondingly, no growth was observed in German beer with alcohol contents over 5.5 and 6.5% (v/v; Back, 1981; Seidel et al., 1979).

Utilization of different carbon sources by *M. cerevisiae* is presented in Table 2. The carbohydrate spectrum of *M. cerevisiae* is very narrow compared with that of *M. elsdenii*. The brewery isolates do not utilize glucose or maltose, but like *M. elsdenii*, they can grow in sugar-free medium although growth is very poor (Engelmann and Weiss, 1985; Weiss et al., 1979). With respect to the fermentation of carbohydrates, the brewery isolates of *Megasphaera* form a very uniform group. Like *Pectinatus*, they can utilize lactate and, hence, lactic acid bacteria could in practice facilitate their growth.

Metabolic end products of *Megasphaera* spp. are *iso-* and *n*-butyric acid, *iso-* and *n*-valeric acid, acetic, propionic and caproic acids (Engelmann and Weiss, 1985; Haikara, 1985a; Weiss et al., 1979; Table 1). The predominant end product from lactate is *n*-valeric acid. In beer, the main metabolic product is *n*-butyric acid (Haikara and Lounatmaa, 1987). The production of caproic acid is a typical feature of this genus. All *Megasphaera* species produce H_2S (Engelmann and Weiss, 1985; Weiss et al., 1979). Owing to the mixture of various fatty acids and H_2S, the flavor of contaminated beer is particularly unpleasant.

All *Megasphaera* strains isolated from beer are catalase-, benzidine- and Voges-Proskauer-negative; do not hydrolyze urea, arginine, gelatin or esculin; do not reduce nitrate; and do not form indole (Weiss et al., 1979).

Exceptional in that it exhibits increased heat resistance at low pH in wort, *M. cerevisiae* DSM 20461 was found to be more resistant to heat (on the basis of D–50 values) at pH 4 than at pH 5.2 or 6.0 (Watier et al., 1996a).

Physiological and Biochemical Properties of *Zymophilus*

Zymophilus species are obligately anaerobic, motile, nonsporeforming, Gram-negative rods. The optimum temperature for growth is 30°C (see Isolation). Both species ferment glucose to acetic and propionic acids (Table 1). Trace amounts of lactic acid are produced by *Z. paucivorans*. Physiological properties and G+C contents of both *Zymophilus* species are listed in Table 2 (Schleifer et al., 1990). The data is based on ten *Z. raffinosivorans* strains isolated from pitching yeast and brewery waste and on four *Z. paucivorans* strains isolated from pitching yeast. *Zymophilus* species are not only morphologically quite different, but they also differ in the utilization of xylose, rhamnose, xylitol, raffinose, melibiose and inositol (Table 2).

CHAPTER 1.3.3

The Genus *Selenomonas*

ROBERT B. HESPELL, BRUCE J. PASTER AND FLOYD E. DEWHIRST

Species of *Selenomonas* are defined as anaerobic, Gram-negative, curved or crescent-shaped rods that are motile by means of a tuft of flagella originating from the inner curvature of the cell. Selenomonads have been isolated from the rumen and ceca of mammals, and the human oral cavity. Depending upon the health or diet of the host, these bacteria can constitute a significant proportion of the total microbial population. In general, selenomonads are obligately saccharolytic, although some strains ferment lactate or amino acids. It has been suggested that the role of ruminal and intestinal selenomonads involves the fermentation of soluble sugars and lactate in their natural environments. Oral selenomonads may play a role in the pathogenesis of periodontal disease in humans. The first classification of selenomonads was by Miller (1887), who designated strains from the human mouth as *Spirillum sputigenum*, but the present classification system places these organisms in the genus *Selenomonas* as *S. sputigena* (Bryant, 1984; Johnson et al., 1985). As a result of recent findings, however, at least six species of oral selenomonad have been recognized (Moore et al., 1987). Phylogenetic studies based on 16S ribosomal RNA sequence analysis have shown that species of *Selenomonas* are closely related to the bacteria *Centipeda periodontii, Pectinatus cerevisiiphilus*, and *Sporomusa paucivorans*. The selenomonads are more distantly related to anaerobic Gram-negative cocci of the genera *Veillonella* and *Megasphaera*. Selenomonads, *Veillonella* and related bacteria comprise a phylogenetic grouping which is more closely related to Gram-positive bacteria than to typical Gram-negative bacteria.

Habitats

Selenomonads have been observed in and isolated primarily from the rumen, the human mouth, and the cecum of mammals (Table 1). Gram-negative organisms having the cell morphology and flagellar arrangement typical for selenomonads have also been observed in river water (Leifson, 1960), and recently selenomonads have been isolated from anaerobic sewage sludge (Nanninga et al., 1987) and bog water (Harborth and Hanert, 1982). Selenomonads were probably first observed by Antonie van Leeuwenhoek in gingival scrapings from the human mouth (Dobell, 1960). Traditionally, speciation within *Selenomonas* has been based upon the habitat from which the strain was isolated (Buchanan and Gibbons, 1974; Lessel and Breed, 1954). Although helpful, this criterion has been largely supplanted by more adequate cytological, biochemical, and molecular criteria.

Selenomonads appear to be part of the normal indigenous microflora of human gingival crevices and are often more abundant in those persons having clinically detectable gingivitis or peridontal disease. Oral selenomonads may play a role in peridontal disease, inasmuch as lipopolysaccharide purified from these bacterial species has been shown to possess several endotoxic properties in mice (Kurimoto et al., 1986). Some occurrences of *S. sputigena* and other selenomonads in human septicemia have been reported (MacCarthy and Carlson, 1981; Pomeroy et al., 1987).

Selenomonads isolated from the rumen are usually shown to be strains of *S. ruminantium*. These organisms are routinely observed and isolated from rumen contents of cows and sheep. (Bryant, 1956; Hobson and Mann, 1961; Prins, 1971). In general selenomonads are more numerous in animals fed rations such as grains, which contain rapidly fermentable carbohydrates, than they are in animals fed silage or straw (Caldwell and Bryant, 1966). In addition to the fermentation of soluble carbohydrates, rumen selenomonads have other important roles in the rumen. These organisms are among the most important members of the glycerol-fermenting species of ruminal bacteria in sheep (Hobson and Mann, 1961) and in cattle (Bryant, 1956). While lactate is fermented by only a few species of ruminal bacteria, many ruminal selenomonad strains ferment lactate. Often, these strains are designated as *S. ruminantium* subspecies *lactilytica* and are almost phylogenetically identical to *S. ruminantium* (Fig. 1). Lower ruminal pH and increased lactate formation resulting from bloat or high-grain feeding, can lead to a substantial increase of ruminal selenomonads. Urea present in saliva and feedstuffs is degraded in the rumen by urease to form ammonia, a

Data from Nanninga et al. 1987; Kingsley and Hoeniger (1973); and Moore et al. 1987.
Fig. 1. Phylogenetic tree for the selenomonads and related bacteria. The scale indicates a 5% difference in nucleotide sequence, as determined by taking the sum of all branch lengths connecting two species. (Sequences for *S. paucivorans* and *M. elsdenii* courtesy of C. R. Woese.)

major nitrogen source for growth of many rumen microorganisms. *S. ruminantium* probably contributes to the hydrolysis of urea because urease-producing strains are commonly isolated (Wozny et al., 1977).

Selenomonad strains that have been phenotypically classified as *S. ruminantium* constitute a significant part of the intestinal microbial populations of swine. Approximately 21% of the total bacterial isolates from cecal contents of healthy swine were strains of *S. ruminantium* (Robinson et al., 1981). *S. ruminantium* strains were found to represent about 5% and 15% of the total bacteria associated with the epithelial tissue of the colon in healthy and dysentery-infected swine, respectively (Robinson et al., 1984). Although this last study did not find selenomonad strains in luminal contents of the colon, these organisms have been detected in swine feces (Salanitro et al., 1977). Presumably, a functional role for selenomonads in the swine intestine involves fermentation of soluble sugars as occurs with these organisms in the rumen. The dominance of *S. ruminantium* strains in the swine intestine may

be related to the availability of lactate. The swine of the small intestine can contain high levels of lactate (15 to 20 mM) and lactate levels decrease almost 10-fold upon reaching the cecum (Imoto and Namioka, 1978). In this regard, all of the selenomonad strains isolated from cecal contents have been lactate-fermenting strains, namely *S. ruminantium* subsp. *lactilytica* (Robinson et al., 1981). Lactate may also be available to *Selenomonas* strains that adhere to the colon wall since other adherent bacteria include lactate-producing species such as *Lactobacillus and Enterococcus* (Robinson et al., 1984).

Selenomonas species have frequently been observed and isolated from the cecum of a number of small rodents. The study by Ogimoto (1972) indicated that about 5% of the total bacterial isolates from rat cecal contents were selenomonads. All their rat strains could ferment any one of a number of sugars, including cellobiose; propionate was the major fermentation acid. With freeze-fracture electron microscopic techniques, selenomonads could be seen in the rat cecum submucosa. Gram-negative organisms that have the cell morphology and flagellar arrangement typical for selenomonads have been observed in cecal contents of squirrels. These organisms were enumerated and isolated from cecal contents of the 13-lined ground squirrel (*Citellus tridecemlineatus*) and shown to be as high as 1×10^9 to 1×10^{10} cells per gram of cecal contents (Barnes and Burton, 1970). In addition, it was shown that these selenomonads constituted 18% or more of the total viable cells of the cecal contents of both active and hibernating squirrels. All selenomonad strains from squirrels could ferment glucose and some strains could ferment starch, but further biochemical characteristics of these strains have not been determined. Many investigators have observed selenomonads in the cecal contents of guinea pigs (Kingsley and Hoeniger, 1973; Robinow,

1954). These organisms have been designated as *S. palpitans* (Simons, 1922), but since the organisms have not been isolated or grown in pure culture, this classification is questionable. However, electron micrographs of "*S. palpitans*" indicate it is a selenomonad which differs in some respects in cell morphology from *S. ruminantium* (Kingsley and Hoeniger, 1973).

The isolation of selenomonads from nonmammalian environments has been reported only on one occasion; using lactate and sulfate enrichment cultures, a selenomonad strain was isolated from ditch water from a bog habitat (Harborth and Hanert, 1982). This strain was phenotypically similar to *S. ruminantium* except it has a lower optimal growth temperature (25°C) and produces catalase. The authors suggested it be considered *S. ruminantium* subspecies *psychrocataligenes*. Selenomonad strain DSM 3853 (strain DKglu16) was isolated from glutamate-plus aspartate-limited chemostat cultures inoculated with anaerobic sewage sludge (Nanninga et al., 1987). Because this strain fermented only amino acids and differed in many other ways from other *Selenomonas* species, it was named *S. acidaminophila*. These studies suggest that selenomonads may exist in a number of natural, anaerobic habitats.

Isolation

Selective Enrichment and Isolation

Enrichment and selection procedures have been effectively developed only for the isolation of selenomonad strains from ruminal contents. Ruminal organisms can be selectively isolated using SS medium that has mannitol as the only added carbohydrate (Tiwari et al., 1969). The selective factors of SS medium are: 1) the use of mannitol as the main energy source, (since few species of ruminal bacteria can ferment this sugar); 2) the pH of the medium is 6.0, which does not affect selenomonad growth, but inhibits growth of many other species; and 3) the medium contains no branched-chain volatile fatty acids or heme, and either or both of these compounds are required for the growth of many other ruminal bacteria. Substitution of glycerol or lactate for mannitol in SS medium might allow for preferential isolation of selenomonad strains commonly designated as *S. ruminantium* subspecies *lactilytica*.

Selective Medium (SS) for Isolation of *Selenomonas ruminantium* (Modified from Tiwari et al., 1969)

Mannitol	0.2 g
Trypticase	0.5 g
Yeast extract	0.1 g
Sodium acetate	0.1 g
FeSO$_4 \cdot$ 7H$_2$O	0.1 g

Mineral S solution (see below)	4.1 ml
n-Valeric acid	0.05 ml
Distilled water	92.5 ml
L-Cysteine · HCl solution (2.5%) (see below)	1.0 ml
Sodium carbonate solution (8%) (see below)	2.5 ml

The L-cysteine solution is prepared with oxygen-free distilled water under a nitrogen-gas phase. Both the sodium carbonate solution and final SS medium are prepared and equilibrated under a carbon dioxide gas phase. The L-cysteine and sodium carbonate solutions are autoclaved separately and added to the cooled medium. The composition of the mineral S solution is: monobasic potassium phosphate, 12.0 g; ammonium sulfate, 6 g; sodium chloride, 12.0 g; magnesium sulfate heptahydrate, 2.5 g; calcium chloride dihydrate, 1.6 g; and distilled water to a final volume of one liter. This solution is stable when stored at 5°C.

In regard to other species of *Selenomonas*, some enrichments for these organisms appear possible from samples of anaerobic sludge, bog water, or highly eutrophic waters. With such samples, the use of glutamate or aspartate as the main carbon source may lead to enrichment of *S. acidaminophila* strains (reference is not an exact match Nanninga et al., 1982), whereas use of lactate may result in enrichment of *S. ruminantium* strains (Harborth and Hanert, 1982).

MacDonald and Madlener (1957) examined several methods for isolating oral selenomonads. These authors found that complex media containing sodium lauryl sulfate (0.01%) or sodium oleate (0.15%) in addition to sheep serum (10%) would inhibit the growth of many microorganisms present in gingival scrapings, but would not affect selenomonad growth. Nonselective media, such as commercially available blood agar, can sometimes be used for the isolation of oral selenomonads. In certain subgingival sites that possess clinical signs of periodontitis, oral selenomonads can represent 10–30% of the total bacterial population (S. S. Socransky, personal communication). Appropriate dilutions of clinical samples are plated onto agar media and incubated under an atmosphere of 80% N$_2$/10% CO$_2$/10% H$_2$. Identification of these motile bacteria is initially based upon colony morphology. Since cells are able to migrate through solid medium with lowered concentrations of agar, colonies with a spreading, fuzzy morphology form. Some species of *Selenomonas* or *Centipeda* form a hazy zone of growth on the surface of the agar medium (Lai et al., 1983).

Cultivation Media

The nutrient requirements of *S. ruminantium* strains are rather simple, and most, if not all, strains can be grown anaerobically in chemically defined media containing glucose, minerals, B vitamins, ammonia, sulfide, and a volatile fatty acid (usually n-valerate), under a carbon dioxide

atmosphere (Bryant and Robinson, 1962; Kanegasaki and Takahashi, 1967; John et al., 1974; Tiwari et al., 1969). More complex media containing yeast extract and trypticase, such as those used for *Succinivibrio dextrinosolvens* (see The Family Succiaivibrionaceae in Volume 3), will support growth of *S. ruminantium* strains. These complex media probably can support growth of *S. acidaminophila*, but glutamate, aspartate, pyruvate, or lactate would be needed as the energy source (Nanninga et al., 1987). For *S. ruminantium*, sulfide or cysteine serve as sole sulfur sources. Substances that can serve as sole nitrogen sources include ammonia, urea, certain single amino acids (cysteine, serine, threonine, aspartate, histidine, glutamate, and valine), or the purines adenine and uric acid, Some strains utilize urea or ammonia as a sole nitrogen source, but many strains do not. When lactate is the energy source, biotin and *p*-aminobenzoic acid satisfy the vitamin requirements; aspartate, malate, or fumarate are required for growth and aromatic amino acids may be stimulatory to growth (Linehan et al., 1978).

The nutritional features of most human oral species of *Selenomonas* have not been studied in detail, as has been done with *S. ruminantium*. Most of these species have been isolated on very complex media, such as brain-heart infusion agar or on this medium supplemented with 5% rabbit blood or serum. Rich media such as peptone-yeast extract-glucose often support growth of many of these species (Moore et al., 1987).

Preservation of Cultures

Most species can be maintained for long periods by storing cultures in liquid nitrogen or ultracold freezers (Hespell and Canale-Parola, 1970). Depending upon the strain, preservation by lyophilization under anaerobic conditions may be possible. Alternatively, short-term storage (6 to 15 months) may be possible by placing glycerol-containing cultures in normal (−20°C) freezers (Teather, 1982).

Identification

Phenotypic Properties

Quite often, newly isolated bacterial strains can be identified as *Selenomonas* based on the characteristic cell shape and tumbling motility of these species. All species are obligately anaerobic, motile, nonsporeforming, Gram-negative rods. The cells are usually curved or cresent-shaped and have a tuft of flagella that originates from the concave side of the cell, as revealed by Leifson flagella staining or by electron micros-

copy. Strains of the related genus *Pectinatus* have a similar curved-cell morphology, but the flagella are arranged linearly along the entire length of the concave side of the cell (Lee et al., 1978). *Centipeda* strains are Gram-negative, curved or helical rods. However, the flagella *Centibeda* are inserted in a line or stop that spirals around the cell, resulting in bundles that arise from both cell sides, giving a centipede-like appearance to the cell (Lai et al., 1983). A major characteristic of all known *Selenomonas* species is that they produce both acetate and propionate as major fermentation acids. Many strains also form small amounts of lactate and/or succinate (Table 2).

Species of *Selenomonas* have varying types of colony morphologies and cell sizes. Most strains of *S. ruminantium* produce large colonies (3- to 6-mm diameter) that are smooth, entire, slightly convex, and light tan to white in color. Often, these colonies have a gray to black appearance (due to hydrogen sulfide production) starting in the center of the colony. The cells are usually 1 μm by 2.0 to 4.0 μm long, but *S. ruminantium* subspecies *lactilytica* strains can be 2.0–3.0 μm by 5.0–10.0 μm long. Many *S. ruminantium* strains have carbohydrate granules in the cytoplasm, and cells may be strongly iodophilic (Prins, 1971) but no capsular material is present.

With newly isolated strains, *S. sputigena* colonies on blood-agar media are generally small (0.5 to 1.2 mm in diameter), smooth, convex, and gray to gray-yellow in color. Larger colonies tend to have an irregular edge and translucent appearance. Most of the other oral selenomonad species form minute colonies (0.5–1.0 mm in diameter) that are shiny, smooth, and colorless to white. A spreading growth over the entire plate is not uncommon for several species. The cell sizes of most oral selenomonad species range from about 1.0–1.4 μm wide by 3.0–5.5 μm long.

Species of *Selenomonas*, *Pectinatus*, and *Centipeda* can be differentiated from one another on the basis of a number of phenotypic traits (see Table 2). *C. periodontii* is the only species listed that has a bilateral flagella arrangement and that does not form acetate as a major fermentation acid, although trace amounts of acetate can be made by some strains. *P. cerivisiiphilus* and *S. ruminantium* are the only listed species to produce hydrogen sulfide. *P. cerivisiiphilus* differs from *S. ruminantium* by its linear array of flagella and its inabilities to ferment sucrose and hydrolyze esculin (Lee et al., 1978). *S. acidaminophila* differs from all other listed species by its inability to ferment sugars, by using only lactate, pyruvate, glutamate, and aspartate, and by being able to hydrolyze gelatin. *S. ruminantium* is the only *Selenomonas* species capable of fermenting cellobiose. *S. infelix* and *S. dianae* are the only oral *Selenomonas* species capable of esculin

Table 2. Characteristics that differentiate species of *Selenomonas*, *Pectinatus*, and *Centipeda*.[a]

hydrolysis, and these two species can be separated on the basis of acid production on trehalose. With respect to the esculin-negative oral *Selenomonas* species, *S. flueggei* and *S. sputigena* are both positive for acid from lactose and can be separated on the basis of acid from mannitol, whereas *S. artemidis* is negative for acid from lactose. *S. noxia* is negative for all of the previously mentioned traits of *Selenomonas* species, but growth is abundant in a peptone-yeast extract medium containing glucose, mannose, sorbitol, or sorbose.

Phylogeny

The GC content of the DNA from *Selenomonas* species ranges from 48 to 58 mol% (see Table 1). *S. acidaminophila* has the lowest value, whereas *S. ruminantium* strains vary from 49 to almost 54 mol%. The oral species of *Selenomonas* have only a narrow range of 53 to 58 mol%, but it is clear from the results of DNA-DNA hybridization (Table 3) that these strains are, in fact, separate species.

The phylogeny of species of *Selenomonas* and related bacteria has been determined by using 16S rRNA sequence analysis (Dewhirst et al., 1989). Complete 16S rRNA sequences of these bacteria were compared with the rRNA sequences of over 250 other bacterial species (Paster and Dewhirst, unpublished observations). From these data, a phylogenetic tree was constructed (Fig. 1). The microorganisms tested fall into two major groups—*Selenomonas* and related bacteria occupy one branch, and *Veillonella* and related bacteria are on the other. The *Selenomonas* group is phylogenetically coherent with interspecies homology levels of 90 to 99%. *Selenomonas dianae*, *S. infelix*, *S. flueggei*, *S. noxia*, *S. artemidis*, and *Centipeda periodontii* form a very tight cluster with a homology range of 96 to 99%. *Selenomonas sputigena* and *S. ruminantium* have an average sequence homology of 94% with members of this cluster. Aside from its unusual flagellation, *C. periodontii* is phenotypically similar to other members of the genus *Selenomonas*.

Pectinatus cerevisiiphilus, a Gram-negative, anaerobic, motile rod originally isolated from spoiled beer, is related to the *Selenomonas* group, but with an average homology value of only 91% (for further information see Chapter 91). *Sporomusa paucivorans* is an anaerobic, Gram-negative, sporeforming rod. This organism is related to the selenomonads at an average homology level of 90%.

In the other major branch of this tree, *Veillonella dispar* and *V. parvula*—aerobic, Gram-negative cocci isolated from humans—are very closely related to each other with 99% sequence homology. *Megasphaera elsdenii* (see *Pectinatus*, *Megashaera* and *Zymophilus* in this Volume), an anaerobic, large, Gram-negative coccus isolated from humans and the ovine rumen, is related to *Veillonella* at a level of 92% homology. Species within these two bacterial genera are related to members of the *Selenomonas* branch with an average homology of 88%. The close relationship between motile, curved rods and nonmotile cocci may seem unusual, but there are phenotypic traits that unify this diverse group. One of the more convincing characteristics is that species of *Selenomonas*, *Sporomusa*, *Veillonella*, and *Megasphaera* all possess the one of the diamines, either cadaverine or putrescine, which are covalently bound to their peptidoglycan (Stackebrandt et al., 1985).

It has been previously shown that the genera *Selenomonas* and *Veillonella* share a branch with the Gram-positive bacteria (Stackebrandt et al., 1985). Members of these two groups both have an average 16S rRNA sequence homology of 85% with the Gram-positive bacteria, as represented by species of *Clostridium*, *Bacillus*, and *Enterococcus*, but only 79% sequence homology with Gram-negative bacteria such as *E. coli* and related bacteria (Fig. 2). Other bacterial groups, such as those containing the spirochetes, bacteroides, and radiation-resistant bacteria, branch deeper in the tree (unpublished observations) with even lower sequence homologies (e.g., <75%) with the selenomanads. From these data, it is evident that the selenomonads should be removed from the *Bacteroidaceae,* their current taxonomic placement in *Bergey's Manual of Systematic Bacteriology*. In general, a sequence homology of less than 80% indicates that the bacteria compared are in different major taxonomic divisions.

Table 3. Percentage of homology from DNA-DNA hybridizations of oral *Selenomonas* species.

Species	S. artemidis	S. noxia	S. flueggei	S. infelix	S. sputigena	S. dianae
S. artemidis	100					
S. noxia	24	100				
S. flueggei	13	22	100			
S. infelix	15	20	18	100		
S. sputigena	4–8	13	5	6	100	
S. dianae	14	28	15	30	4–8	100

Data from Moore et al. (1987).

Now that 16S rRNA sequences are known (see below), it will be possible to develop short DNA probes targeted for signature regions of 16S rRNA. These probes can be used to identify new strains or species isolated from environmental samples. Ultimately, these probes will allow for the rapid identification of selenomonads directly from samples without in vitro cultivation. Family-specific and species-specific DNA probes have been already used to identify RNA isolated from selenomonads (Dewhirst et al., 1989).

Physiological Traits

Many biochemical and physiological studies have been done with *S. ruminantium*, but not with the oral species of *Selenomonas*. Early studies on isolation of ruminal bacteria did not indicate that *S. ruminantium* produced hydrogen gas as a fermentation product. However, when this organism was grown in the presence of a hydrogen-utilizing bacterium, namely a methanogen, (Scheifinger et al., 1975b). As a consequence, considerably less lactate and propionate were produced from glucose fermentation. *S. ruminantium* also changes the array of fermentation acids made as function of growth rate, with acetate and propionate dominating at low growth rates and lactate at high growth rates (Hobson, 1965). These shifts in fermentation products are correlated with less ATP formation and can be largely explained by the effects of pyruvate on the activity of the intracellular lactic acid dehydrogenase (Scheifinger et al., 1975a; Wallace, 1978). At higher growth rates, intracellular pyruvate pools probably increase and this compound causes a homotropic activation of lactate acid dehydrogenase, resulting in higher rates of lactate formation. The other major fermentation acid, propionate, has been shown to be formed via the succinate pathway (Paytner and Elsden, 1970). Propionate formation most likely involves generation of ATP via formation of a proton-motive force, since *S. ruminantium* was one of the first anaerobes to be shown to possess cytochromes, mainly of the cytochrome-*b* type (DeVries et al., 1974).

Ammonia and urea play central roles in ruminal nitrogen metabolism. *S. ruminantium* is one of the major ureolytic bacteria in the rumen (Wozny et al., 1977). Studies on ammonia assimilation and glutamate formation in *S. ruminantium* indicate this organism possesses both the glutamate dehydrogenase and glutamine synthetase pathways for ammonia assimilation (Smith et al., 1980). In fact, this study was the first to show presence of a nonadenylylation control mechanism for glutamine synthetase in a Gram-negative organism. However, it was shown later that this enzyme and urease were coordinately controlled (Smith et al., 1981), as in other bacteria.

One of the first detailed studies on survival of anaerobic bacteria under nongrowing conditions was with *S. ruminantium*. Washed cell suspensions obtained from glucose-limited chemostats were found to lose viability very rapidly, with about a 50% loss in 2.5 hours (Mink and Hespell, 1981). The viability losses could not be attributed to cell lysis but correlated with rapid declines in cellular DNA, RNA, and protein. Similar effects were found with cells grown under nitrogen-limited conditions but better survival times were observed that correlated with growth rates (Mink et al., 1982). During starvation, the cells produced trace amounts of acetate as the only fermentation product. In addition, it was shown that the cellular levels of urease, glutamine synthetase, and glutamate dehydrogenase remained relatively stable despite loss of cell viability.

Applications

At present, no biotechnological applications have been made with *Selenomonas* species. However, a recent paper on the kinetics of glucose fermentation by *S. ruminantium* suggests that this organism might have commercial application for the production of lactic acid (Shimizu et al., 1989). A new species of the genus *Selenomonas* has been described by Schleifer et al. 1990. *Selenomonas lacticifex* was isolated from pitching yeast and can ferment glucose to lactic acid as major product.

CHAPTER 1.3.4

The Genus *Sporomusa*

JOHN A. BREZNAK

Introduction

The genus *Sporomusa* was created in 1984 (Möller et al., 1984) to accommodate a number of strains of anaerobic, homoacetogenic bacteria distinguished by having a Gram-negative cell wall and an ability to form endospores-two properties whose coincidence is uncommon in the microbial world. The genus name means "spore-bearing banana," and reflects the slightly curved, rod shape of the cells. Two species, *S. sphaeroides* and *S. ovata*, were distinguished from each other on the bases of endospore shape, substrate utilization pattern, and G+C content of their genomic DNA. Subsequently, five additional species were revealed, and the phylogenetic position of *Sporomusa* was clarified. This chapter will update our understanding of *Sporomusa*, including several of their more notable properties: their common occurrence in anoxic (and even seemingly well-aerated) environments, their ability to grow by decarboxylation of organic acids, and their possession of unusual corrinoids.

Phylogeny

The first insight into the phylogeny of *Sporomusa* came from analysis of 16S rRNA oligonucleotide catalogues (Stackebrandt et al., 1985). Results revealed that *S. sphaeroides* and *S. ovata* bore a distinct, but remote, relationship to the Gram-negative bacteria, *Selenomonas* and *Megasphaera*, and to Gram-positive bacteria of the "*Clostridium* subdivision." This was borne out in subsequent analyses of additional species, and in a comprehensive reexamination of the phylogeny of the genus *Clostridium* and close relatives. Collins et al. (1994) assigned *Sporomusa* to "Cluster IX"—a deeply branching assemblage of bacteria in the "Clostridium phylum"-along with a heterogeneous collection of other spore-forming and nonspore-forming organisms, many of which were Gram negative. At that time, Cluster IX included *Acidaminococcus*, *Clostridium quercicolum* (now *Dendrosporobacter quercicolus*; Strömpl et al., 2000), *Megasphaera*, *Pectinatus*, *Phascolarctobacte-*

rium, *Quinella*, *Selenomonas* and *Zymophilus paucivorans*. It has since become clear that a number of other isolates obtained over the past ten years can be added to this cluster, including *Acetonema* (Kane and Breznak, 1991), *Anaeromusa* (Baena et al., 1999), *Anaeroarcus*, *Anaerosinus* and *Anaerovibrio* (Strömpl et al., 1999), *Centipeda periodontii* (Sawada et al., 1999), *Dialister* (Willems and Collins, 1995b), *Mitsuokella multacida* (Willems and Collins, 1995a), *Propionispora* (Biebl et al., 2000), *Succiniclasticum* (Van Gylswyk, 1995), *Succinispira* (Janssen and O'Farrell, 1999), *Schwartzia* (Van Gylswyk et al., 1997), and *Veillonella* (Willems and Collins, 1995b). This phylogenetic group is sometimes referred to as the "*Sporomusa* branch" (Willems and Collins, 1995b), the "*Sporomusa-Pectinatus-Selenomonas* group" (Biebl et al., 2000), or by similar phrases.

Taxonomy

In the forthcoming volume 2 of the second edition of *Bergey's Manual of Systematic Bacteriology*, *Sporomusa* will likely be regarded as a genus within Family VII (Acidaminococcaceae) of Order I (Clostridiales) of class I ("Clostridia") of Phylum BXIII (Firmicutes) of the Domain Bacteria (Garrity and Holt, 2000). At this writing, the genus *Sporomusa* contains seven named species. Phenotypic properties useful in distinguishing between them are given in Table 1.

Habitat

Sporomusa has been isolated from anoxic sediments of freshwater rivers, lakes, creeks and ditches (Möller et al., 1984; Hermann et al., 1987; Dehning et al., 1989; Sass et al., 1998), and anoxic soil from rice paddy microcosms (Rosencrantz et al., 1999); from soils and silage (Möller et al., 1984; Kuhner et al., 1997); from sugar beet factory and distillery wastewater (Möller et al., 1984; Ollivier et al., 1985); from horse and cattle dung (Möller et al., 1984); and from the gut of

wood-eating termites (Breznak and Switzer, 1986; Breznak et al., 1988). Inocula for the isolations cited above were obtained from many parts of the world. No reports exist of *Sporomusa* strains isolated from thermal habitats or from brackish or marine habitats, although there is no reason to think that such strains should not exist. Indeed, *S. malonica* was found to grow in a "brackish water" medium containing 10 g of NaCl and 1.5 g of $MgCl_2 \cdot 6 H_2O$ per liter (Dehning et al., 1989).

Isolation

Enrichment Cultures

At present there is no enrichment procedure that is entirely specific for *Sporomusa*. However, selectivity can in principle be enhanced by exploiting the resistance to heat that is typical of bacterial endospores, followed by inoculating the heat-treated source material into an anoxic medium that is low in sulfate (to discourage growth of sulfate-reducing bacteria) and that contains a substrate reasonably selective for *Sporomusa*. Heat treatment is done by pasteurization at 80°C for 10–15 minutes. A variety of substrates can be used as energy sources by one or more species of *Sporomusa*, including molecular hydrogen (H_2) + carbon dioxide (CO_2), various sugars (e.g., fructose), organic acids (e.g., lactate), glycols (e.g., ethylene glycol, 2,3-butanediol), alcohols (e.g., methanol, ethanol), and *N*-methyl (e.g., betaine) and *O*-methyl (e.g., methoxylated aromatic) compounds. However, in liquid enrichment cultures, *Sporomusa* might be accompanied by clostridia or other endospore-forming bacteria (e.g., *Acetonema*; Kane and Breznak, 1991), that also use some of these same compounds. Substrates that support good growth of all species of *Sporomusa* are $H_2 + CO_2$ ($H_2/CO_2 \geq 2/1$, v/v) and methanol + CO_2 (molar ratio of methanol/$CO_2 \geq 2/1$), which are used by all species of the genus. When methanol is used, the concentration in the medium should be ≤ 5 mM (to avoid toxicity) and replenished as necessary. Whether these or other selective substrates are employed, CO_2 should constitute 20% or more of the gas phase, wherein it can serve as: 1) a major C source for acetogenesis (e.g., with H_2 or ethanol as the oxidizable substrate); 2) a ready source of the carboxyl group of acetate (e.g., in combination with substrates such as methanol, betaine or methoxylated aromatics, which provide preformed methyl groups); or 3) a readily available substrate for carboxylation reactions involved in biosynthesis. Carbon dioxide in the gas phase should be balanced by an appropriate amount of HCO_3^- in the liquid phase

to buffer the medium at pH 7 (Breznak and Costilow, 1994b), which is at or near the pH optimum of all strains tested. An incubation temperature of 30–35°C will permit growth of all known species of *Sporomusa*. Butyl rubber-stoppered tubes or bottles for isolation and enrichment cultures are those used for cultivation of methanogens and other anaerobes and are available commercially (Miller and Wolin, 1974; Balch and Wolfe, 1976; Hermann et al., 1986).

The one-carbon compounds formate and carbon monoxide (CO) are also used by some species of *Sporomusa*, but growth with formate is sometimes poor, whereas CO can be toxic. Consequently, growth and/or acetate production above that in control (no substrate) enrichments may be difficult to detect with these substrates. Targeted enrichment and isolation of *S. acidovorans*, *S. malonica* and *S. termitida* is, in principle, possible by using sodium succinate as an energy source. These species can grow by decarboxylation of succinate to propionate $+CO_2$. *Spormusa malonica* and *S. termitida* also will grow by decarboxylation of malonate to acetate $+CO_2$. However, the energy yield from such decarboxylations is low, so the growth rate and yield of cells per mole of substrate will also be low. The use of *N*-methyl compounds (e.g., betaine) and aryl *O*-methyl compounds (e.g., 3,4,5-trimethoxybenzoate) as enrichment substrates may also provide some selectivity. They are a ready source of the methyl-group of acetate by demethylation and, by oxidation of some of the released methyl groups, of electrons for CO_2 reduction to the carboxyl group of acetate. Betaine was used by pure cultures of all species tested, i.e., *S. sphaeroides* and *S. ovata* (Möller et al., 1984; Kamlage et al., 1993b), *S. paucivorans* (Hermann et al., 1987), *S. termitida* (Breznak et al., 1988) and *S. silvacetica* (Kuhner et al., 1997). Likewise, *O*-methylated aryl substrates were used by *S. ovata* (Stupperich and Konle, 1993), *S. silvacetica* (Kuhner et al., 1997) and *S. termitida* (Breznak et al., 1988).

For enrichment of *S. paucivorans* (the only species of *Sporomusa* that does not appear to form endospores; Hermann et al., 1987), or for ecological studies where all viable *Sporomusa* cells are to be enumerated by using most probable number (MPN)-type dilution series, heat treatment of the inoculum (e.g., pasteurization) should be avoided. However, it is worth noting that with the exception of *S. sphaeroides* and *S. ovata*, most other species of *Sporomusa* were isolated from enrichment cultures established with unpasteurized inocula and $H_2 + CO_2$ or methanol + CO_2 as substrates (*S. malonica* was obtained from a glutarate-degrading consortium and then isolated in agar medium with crotonate as a substrate; Dehning et al., 1989). Following

inoculation, liquid cultures are monitored for growth of putative *Sporomusa* by noting the development of turbidity; by microscopic examination for cells with a morphology that is typical of *Sporomusa* (Fig. 1); and by assay for acetate production (or propionate production if succinate is the substrate). The latter assays can be done by gas chromatography or by high performance liquid chromatography of acidified samples of culture supernatant fluid (see Breznak and Switzer, 1986). If H_2+CO_2 is used as substrate, consumption of this gas mixture is also presumptive evidence of homoacetogenesis and results in the development of negative pressure in the headspace of culture tubes. This can be examined by inserting an H_2/CO_2-filled glass syringe (5 cc or larger capacity, whose barrel has been lubricated with a small amount of light silicone oil) equipped with a 25-gauge needle through the rubber stopper of the culture vessel and by noting the extent to which the plunger moves downward. This simultaneously replenishes the gas used.

A potential confounding factor in enrichment/enumeration of *Sporomusa* is, of course, overgrowth by other homoacetogens, many of which use the same substrates and may be present in the inoculum in greater numbers than *Sporomusa*, or simply grow faster under the conditions employed. With H_2+CO_2, methanol $+CO_2$, or *N*-methyl compounds as substrates, an additional confounding factor is the possible overgrowth of *Sporomusa* by methanogens. To minimize this latter possibility, a specific inhibitor of methanogens, e.g., 2-bromoethanesulfonate (BES) at 1–50 mM (Oremland, 1988), may be included in the medium. However, as yet no systematic studies have been made of the efficacy of BES in media for enrichment of *Sporomusa* on methanogenic substrates. Interestingly, with some substrates, the purposeful addition of methanogens to enrichments actually appears to enhance the recovery of *Sporomusa*. For example, Rosenkrantz et al. (1999) used ethylene glycol, 2,3-butanediol, and 3,4,5-trimethoxybenzoate as substrates in liquid media for MPN-type enumeration of homoacetogens from anoxic rice paddy soils; and from the highest dilution tubes showing growth, strains of *Sporomusa* were isolated. However, the addition of *Methanospirillum hungatei* to analogous tubes with lactate or ethanol as substrate yielded counts of homoacetogens that were several orders of magnitude higher, and from the highest dilution tubes, strains of *Sporomusa* were isolated that were able to use the former three substrates when in pure culture. Why these strains did not initiate growth in higher dilution tubes containing those three substrates in the first place (without exogenously added *M. hungatei*) is not known; neither is the basis for the growth-promoting effect of *M. hungatei* on *Sporomusa*.

Isolation

Isolation of *Sporomusa* is done by streaking the surface of anoxic agar media in "bottle plates" (Hermann et al., 1986) or by diluting samples through a series of "roll tubes" or "shake tubes," which are, in effect, pour plates in a tube. For the former, tubes containing inoculated and mixed molten agar medium are held horizontally under cold water and rolled as the agar solidifies, resulting in a shell of agar medium on the inside surface of the tube. For the latter, the agar is allowed to solidify while the tube is held in a vertical position. When solidified, shake tubes are incubated vertically, but upside (i.e., mouth-side) down. This is done so that the water of syneresis exuded from the agar as it solidifies does not accumulate on the agar surface, through which sterile Pasteur pipettes (with ends drawn out to a tapered capillary) are later inserted to pick isolated subsurface colonies. A detailed description of the roll tube technique is given by Hungate (1969), who also discusses the theoretical and practical aspects of preparation of anoxic medium and methods for the cultivation and manipulation of strict anaerobes in general. Isolation media are then examined for colonies of a size (0.5–4 mm) and morphology (round with an entire margin; white to dark brown) similar to that of known species of *Sporomusa*. Suspected *Sporomusa* colonies are picked, suspended in a small amount of sterile anoxic medium, and
Fig. 1. Morphology of *Sporomusa termitida* strain JSN-2. (a) Phase-contrast micrograph. Bar = 10 μm. (b), (c) Transmission electron micrographs of thin sections. Bars = 0.25 μm. Note endospores (a, b, single arrows) and the outer membrane of the cell wall (c, double arrows). (From Breznak et al., 1988.)

examined by phase contrast microscopy for typical *Sporomusa* cells (Fig. 1a). Smears also can be heat-fixed and Gram-stained for bright field microscopic examination. Presumptive *Sporomusa* colonies are then used as inocula to repeat the isolation procedure until the purity of the cultures is confirmed and the isolates can be completely characterized. If agar media containing H_2+CO_2 as substrate are held in rubber-stoppered tubes or bottles, efforts may be focused on those colonies present in vessels that develop negative pressure in the headspace. Inclusion of a pH indicator in agar media (e.g., 0.01% bromcresol green) may aid in recognizing acid-producing colonies of *Sporomusa* (Braun et al., 1979).

Media

Various culture media have been used for *Sporomusa*: all are more or less similar in composition. As yet no detailed nutritional studies have been done to define the vitamin and/or trace element requirement of individual species. The composition of a basal medium used to enrich for, isolate, and cultivate *S. sphaeroides* and *S. ovata* follows as an example. It would probably, with little or no modification, support the growth of all known species.

Basal Medium for *S. sphaeroides* and *S. ovata* (Möller et al., 1984)

K_2HPO_4	0.348 g
KH_2PO_4	0.227 g
NH_4Cl	0.500 g
$MgSO_4 \cdot 7H_2O$	0.500 g
$CaCl_2 \cdot 2H_2O$	0.025 g
NaCl	2.250 g
$FeSO_4 \cdot 7H_2O$	2 mg
$NaHSeO_3$	15 µg
SL-10 trace element solution (below)	3 ml
Resazurin	1 mg
Distilled water	905 ml

The mixture is deoxygenated by boiling for 5 min, then it is cooled in an ice bath under a stream of nitrogen (N_2)/CO_2 (80/20, v/v) until room temperature is reached. At this point are added 80 ml of $NaHCO_3$ solution (4 g of $NaHCO_3$ in 80 ml of distilled water; gassed with N_2/CO_2 for 20 min) and 2 ml of a 10X stock vitamin solution (below). The medium is then dispensed in tubes or bottles in 9.9 ml amounts (or multiples thereof), sealed under N_2/CO_2 with rubber (preferably butyl rubber) stoppers, and sterilized by autoclaving at 121°C for 20 min. Before use, each 9.9 ml of basal medium is reduced by injecting through the stopper 0.1 ml of Na_2S solution (30 g of $Na_2S \cdot 9H_2O$ per liter distilled water; sterilized by autoclaving under N_2; final concentration in the medium is 1.25 mM) or cysteine solution (30 g of L-cysteine · HCl monohydrate per liter of distilled water; sterilized by autoclaving under N_2; final concentration in the medium is 1.71 mM). This should result in the decolorization of pink resorufin (formed from resazurin upon heating) indicating that the redox potential of the medium is below –51 mV.

SL-10 Trace Mineral Solution (Widdel et al., 1983)

HCl (25% w/v)	10 ml
$FeCl_2 \cdot 4H_2O$	1.5 g
$CoCl_2 \cdot 6H_2O$	190 mg
$MnCl_2 \cdot 4H_2O$	100 mg
$ZnCl_2$	70 mg
H_3BO_3	6 mg
$Na_2MoO_4 \cdot 2H_2O$	36 mg
$NiCl_2 \cdot 6H_2O$	24 mg
$CuCl_2 \cdot 2H_2O$	2 mg
Distilled water	990 ml

The $FeCl_3$ is dissolved in the HCl first, then distilled water is added and the other salts are sequentially dissolved.

10X Stock Vitamin Solution (Wolin et al., 1964)

Biotin	20 mg
Folic acid	20 mg
Pyridoxine HCl	100 mg
Thiamine HCl	50 mg
Riboflavin	50 mg
Nicotinic acid	50 mg
Calcium pantothenate	50 mg
Para-aminobenzoic acid	50 mg
Thioctic acid	10 mg
Vitamin B_{12}	0.1 mg
Distilled water	1,000 ml

When H_2/CO_2 is used as substrate, the medium can be dispensed into culture tubes or bottles under H_2/CO_2 instead of N_2/CO_2 before sterilization. When other substrates are used as energy sources, they are prepared separately as concentrated anoxic stock solutions, sterilized by autoclaving or filtration, and added to the basal medium at a final concentration of 5–50 mM. In this case, a slight adjustment may be made in the initial volume of distilled water used to prepare the basal medium so as to accommodate the volume of stock substrate added later. For solid medium, agar is included at a final concentration of 10–20 g per liter (the lower concentrations preferred for shake tubes; the higher concentrations preferred for roll tubes or bottle plates).

Additional Comments on Media Preparation, Isolation and Cultivation

Degassing of basal medium and other aqueous solutions used for medium preparation also can be achieved by using a water faucet vacuum aspirator for 3–5 minutes while the solution is stirred with a magnetic stirring bar or is swirled by hand. The degassed solution is then held under an O_2-free gas for further manipulations prior to, and following, sterilization. This method is faster than boiling, it eliminates the cooling down time, and it is safer. However, liquids must be held in a vacuum flask, or thick-walled serum bottle or tube during degassing to prevent implosion of the vessel.

Most species of *Sporomusa* require, or are greatly stimulated by, yeast extract and a source

of amino acids. Hence, inclusion in the medium of yeast extract and trypticase, casitone, or casamino acids, at a concentration of 0.5–1 g per liter, may well increase the chances for successful enrichment and isolation of pure cultures.

Although Na$_2$S or cysteine (at 1–2 mM final concentration) are the reducing agents most often used for cultivation of *Sporomusa*, *S. termitida* could not be enriched in media containing these compounds or various alternatives (e.g., titanium citrate, dithiothreitol, amorphous ferrous sulfide, thioglycollate or ascorbic acid). Successful enrichment and isolation of this species was only achieved by using palladium chloride (PdCl$_2$) powder (330 mg per liter) as a catalyst for reduction of the medium by H$_2$, which was a component of the H$_2$+CO$_2$ substrate mixture. After pure cultures were obtained, they could be adapted to grow with dithiothreitol (1 mM final concentration) or other reducing agents (Breznak et al., 1988). Thus, unsuccessful enrichment or isolation of *Sporomusa* might be due to the reducing agent used. It is noteworthy that growth of *S. ovata* is inhibited at sulfide concentrations of 2 mM or greater (Heijthuijsen and Hansen, 1986).

Identification

Recognition of an isolate as a strain of *Sporomusa* is based on: 1) the size (0.4–0.9 × 2–8 mm) and usually curved shape of cells; 2) the formation of endospores by most species; 3) the true Gram-negative character of the cell wall layer; 4) the production of acetic acid as the sole or major product of the fermentation of most substrates, including one-carbon compounds such as H$_2$+CO$_2$, and methanol (+CO$_2$); and 5) their phylogenetic position based on 16S rRNA sequence. None of the named species is known to respire anaerobically with NO$_3^-$ or SO$_4^{2-}$. However, five as-yet-unnamed strains of sulfate-reducing bacteria affiliated with the *Sporomusa* cluster were isolated from an oligotrophic freshwater lake in Germany, and a partial (626-bp) sequence of their 16S rDNA gene revealed *S. termitida* to be their closest relative (95% similarity; Sass et al., 1998). *Sporomusa paucivorans* can reduce sulfide (S0) and cystine, but it does not carry out energy-yielding dissimilatory reduction of these compounds (Hermann et al., 1987). *Sporomusa ovata* is able to dechlorinate tetrachloroethylene (PCE) to trichloroethylene during growth on methanol +CO$_2$, but this does not affect the growth of cells, suggesting that energy cannot be conserved by halorespiration (Terzenbach and Blaut, 1994).

The morphology of *S. termitida* is shown in Fig. 1 as an example. Cells of *Sporomusa* possess a distinct outer membrane, however, it is not yet known whether such membranes contain lipopolysaccharide. Putrescine, cadaverine and spermidine were the major cellular polyamines in a number of *Sporomusa* species; and it appeared that some of these polyamines were covalently linked to peptidoglycan (Hamana, 1999). Vegetative cells are motile by up to 15 flagella inserted laterally. This arrangement imparts a characteristic tumbling type of motility to cells. In *S. sphaeroides*, flagellar rotation was shown to be driven by an electrochemical proton potential (Müller and Bowien, 1995). Membrane-bound cytochromes of the *b*-type and *c*-type (Möller et al., 1984; Breznak et al., 1988; Dehning et al., 1989; Kamlage et al., 1993b; Kuhner et al., 1997) and a respiratory lipoquinone (lipid F; Stackebrandt et al., 1985) have been found in some species. The presence of lipid F appears to be a common characteristic of members of the *Sporomusa-Pectinatus-Selenomonas* phyletic group (Strömpl et al., 2000). In addition, *S. ovata* has been found to possess two unique corrinoids, *p*-cresolyl cobamide (Stupperich et al., 1988) and phenolyl cobamide (Stupperich et al., 1989), which are present in these cells in considerable amounts. These corrinoids differ from all others isolated so far from nature in that their nucleotides consist of phenols rather than a nucleotide base. They appear to be cofactors involved in methyl transfer reactions accompanying the metabolism of methanol and 3,4-dimethoxybenzoate (Stupperich and Konle, 1993). Preliminary analysis of *S. malonica* suggests that it too may contain one or more of these types of corrinoids (Dehning et al., 1989). Endospores of *Sporomusa* are either spherical or oval, terminal or subterminal, and may distend the sporangium (Figs. 1a and c). They are heat-resistant (80°C for 10 min) and contain dipicolinic acid (Breznak et al., 1988; Kuhner et al., 1997).

An H$_2$/CO$_2$-utilizing acetogen that could be mistaken for *Sporomusa* is *Acetonema*, the first and currently only species of which (*A. longum*) was isolated from gut contents of the dry-wood termite, *Pterotermes occidentis* (Kane and Breznak, 1991). *Acetonema longum* is similar to *Sporomusa* in possessing endospores, as well as a Gram-negative-type cell wall. However, *A. longum* is distinct from known species of *Sporomusa* morphologically in having a high cell length-to-width ratio (cells measure 6–60 mm long × 0.3–0.4 mm wide). Moreover, *A. longum* forms abundant amounts of butyrate during glucose fermentation (ca. 1 mol butyrate per mol glucose fermented). *Acetonema longum* also groups within the *Sporomusa-Pectinatus-Selenomonas* group by 16S rRNA sequence analysis, but it sufficiently different from *Sporomusa* phy-

logenetically to warrant recognition as a distinct genus (Kane and Breznak, 1991; Biebl et al., 2000). Other Gram-negative sporeforming anaerobes that resemble *Sporomusa* morphologically are *Dendrosporobacter quercicolus* (Stankewich et al., 1971; Strömpl et al., 2000), *Propionispora vibrioides* (Biebl et al., 2000), and *Sporohalobacter* (Oren et al., 1987). The former two bacteria are also in the *Sporomusa-Pectinatus-Selenomonas* phylogenetic group, but neither uses H_2+CO_2 or one-carbon compounds as energy sources, nor are they homoacetogens. Each produces propionate and acetate from the fermentation of fructose and polyols. Members of *Sporohalobacter* are halophilic anaerobes that produce a variety of products from glucose fermentation and have a relatively low G+C content in their genomic DNA (29.6–31.5%). Analysis of 16S rRNA oligonucleotide catalogues indicated that they were not closely related to *Sporomusa*.

Preservation

The ability of most species of *Sporomusa* to form endospores suggests that sporulated cultures may be stored without special additional treatment for extended periods. Viable subcultures of *S. termitida* have been obtained from broth cultures kept at room temperature for over a year, cultures in which only endospores and ghostlike remnants of vegetative cells were seen (J. A. Breznak, unpublished observation). Hermann et al. (1987) maintained stock cultures of the nonsporing *S. paucivorans* by freezing cells at −80°C in growth medium containing 20% glycerol. Viable *S. termitida* also has been retrieved from cell suspensions frozen at −60°C in fresh medium containing 4% (v/v) dimethyl sulfoxide (J. A. Breznak, unpublished observation).

Physiology

The pathway of acetate formation from one-carbon compounds in *Sporomusa* appears to be the "acetyl CoA pathway," also referred to as the "Wood-Ljungdahl pathway" (Drake, 1994). Virtually all of the enzyme activities associated with this pathway have been demonstrated in *S. sphaeroides*, including CO dehydrogenase, hydrogenase, formate dehydrogenase, formyl-tetrahydrofolate (THF) synthetase, methenyl-THF cyclohydrolase, methylene-THF dehydrogenase, methylene-THF reductase, and an activity capable of ^{14}C-acetate synthesis from $^{14}CH_3$-THF, implying the presence of methyltransferase (Kamlage and Blaut, 1993a; Kamlage et al., 1993b). A methyl transferase activity was

demonstrated in *S. ovata* that transferred the methyl group from methyl-THF to cob(I)alamin in vitro; and two serologically different, corrinoid-dependent *O*-methyl transferases were involved in transferring the methyl group to THF during metabolism of methanol and 3,4-dimethoxybenzoate (Stupperich et al., 1992; Stupperich and Konle, 1993). The methyltransferase involved in methanol metabolism is a 40-kDa protein with firmly bound *p*-cresolyl cobamide. Both CO dehydrogenase and hydrogenase activities were also demonstrated in cell extracts of *S. silvacetica* (Kuhner et al., 1997), and formyl-THF synthetase activity was present in *S. termitida* at a specific activity of 0.084 ± 0.040 U/mg protein (n = 3) when cells were grown on H_2+CO_2 (J. A. Breznak, unpublished observation). Carbonic anhydrase activities varied widely between *S. silvacetica* (0.8 U/mg protein) and *S. termitida* (below the detection limit of the assay), so the importance of this activity to acetogenesis and energy conservation in *Sporomusa* is not entirely clear (Braus-Stromeyer et al., 1997).

The total synthesis of acetate from H_2+CO_2 is an exergonic reaction with a large enough change in free energy to support the growth of all species of *Sporomusa* (equation 1).

$$4H_2 + 2HCO_3^- + H^+ \rightarrow acetate^- + 4H_2O$$
$$(\Delta G^{0\prime} = -104.6 \text{ kJ}) \tag{1}$$
In the Wood/Ljungdahl pathway, one ATP is consumed in the formyl-THF synthetase reaction during reduction of one molecule of CO_2 to the methyl group; and one ATP is formed by substrate-level phosphorylation during conversion of acetyl phosphate to acetate via acetate kinase. Hence, there remains a need for net energy conservation during autotrophic growth, and this is most likely achieved through an ion-translocating ATPase driven in the direction of ATP synthesis by an electrochemical transmembrane ion gradient formed during the reduction of methylene-THF to methyl-THF by methylene-THF reductase (Drake, 1994). In *S. sphaeroides*, cytochromes appear to function as a physiological electron donor for methylene-THF reductase during autotrophic growth, and as an electron acceptor for methyl group oxidation during growth on methanol or other methyl-containing compounds (Kamlage and Blaut, 1993a).

Sporomusa sphaeroides possesses two types of hydrogenase: a soluble activity that mediates electron transfer from H_2 to $NADP^+$, and a membrane-bound, [NiFe] uptake hydrogenase (Dobrindt and Blaut, 1996). The former provides NADPH for the formate dehydrogenase and methylene-THF dehydrogenase reactions. The immediate physiological electron acceptor for

the latter remains to be identified, but the role of this hydrogenase appears to be the donation of electrons to the membrane-bound electron transport chain, inasmuch as washed cell membranes from *S. sphaeroides* mediate an H_2-dependent reduction of a *b*-type cytochrome(s) in the membrane. One working model assumes that generation of a transmembrane electrochemical proton gradient during autotrophic growth results from proton pumping that accompanies electron transfer from H_2 to methylene-THF via cytochromes, or by the release of scalar protons at the periplasmic side of the membrane (Dobrindt and Blaut, 1996).

All species of *Sporomusa* ferment methanol to acetate, but exogenous CO_2/HCO_3^- is required as an electron acceptor for good growth and fermentation of this substrate, as depicted in equation 2.

$$4CH_3OH + 2HCO_3^- \rightarrow 3 \text{ acetate}^- + H^+ + 4H_2O$$
$$(\Delta G^{0'} = -219.8 \text{ kJ}) \qquad (2)$$
In theory, fermentation of methanol should be possible without exogenous CO_2/HCO_3^- if excess reducing equivalents are evolved as H_2 (equation 3).

$$4CH_3OH \rightarrow 2 \text{ acetate}^- + 4H_2 + 2H^+$$
$$(\Delta G^{0'} = -115.2 \text{ kJ}) \qquad (3)$$
However, as the carboxyl group of acetate arises from the oxidation of methanol via THF intermediates, the reduction of protons to H_2 ($E^{0'} = -414 \text{ mV}$) with electrons derived from the oxidation of methyl-THF to methylene-THF ($E^{0'} = -200 \text{ mV}$; Wohlfarth and Diekert, 1991) may require too much ATP to make this option energetically feasible for growth. This concept is discussed in more detail by Heijthuijsen and Hansen (1986).

A fascinating aspect of the metabolism of some species of *Sporomusa* is their ability to obtain energy for growth by decarboxylation of organic acids, even though the associated free energy changes are very small. *Sporomusa malonica* and *S. termitida* can grow by decarboxylation of malonate to acetate +CO_2 (equation 4; Breznak et al., 1988; Dehning et al., 1989).

$$\text{Malonate}^{2-} + H_2O \rightarrow \text{acetate}^- + HCO_3^-$$
$$(\Delta G^{0'} = -17.4 \text{ kJ}) \qquad (4)$$
In *S. malonica*, malonate fermentation proceeds by way of malonyCoA, which is decarboxylated by a biotin-containing enzyme (Dehning and Schink, 1994). These two species, as well as *S. acidovorans*, can also grow by decarboxylation of succinate to propionate +CO_2 (equation 5; Breznak et al., 1988; Dehning et al., 1989).

$$\text{Succinate}^2 + H_2O \rightarrow \text{propionate}^- + HCO_3^-$$
$$(\Delta G^{0'} = -20 \text{ kJ}) \qquad (5)$$
The mechanism by which these decarboxylation reactions couple to ATP formation (a process termed "decarboxylation phosphorylation"; Dimroth and Schink, 1998) is not yet known.

Demethoxylation of methoxylated aromatic compounds can support growth and acetogenesis by *S. termitida* (Breznak et al., 1988), *S. silvacetica* (Kuhner et al., 1997) and *S. ovata* (Stupperich et al., 1996). The *O*-demethylase activity of *S. ovata* grown on 3,4-dimethoxybenzoate was found to have rather broad specificity, being also able to demethylate methoxynaphthols, methoxyfuran and fluoroanisols. Presumably, such substrates will support growth as well. Acrylate groups of methoxylated aromatic compounds are reduced during growth of *S. silvacetica* (Kuhner et al., 1997). However, it is not known whether energy is conserved during such reduction.

Although acetate is the sole or major product from most substrates, propionate is the major product formed from succinate by some species (see eq. 5). In addition, *S. malonica* forms propionate and acetate from malate and fumarate (Dehning et al., 1989), whereas *S. silvacetica* dismutates fumarate to succinate and acetate (Kuhner et al., 1997). *Sporomusa malonica* and *S. paucivorans* form acetate + propionate during fermentation of propanol or 1,2-propanediol, and butyrate + acetate during the fermentation of butanol (Hermann et al., 1987; Dehning et al., 1989), and so resemble *Acetobacterium carbinolicum* (Eichler and Schink, 1984). In addition, *S. paucivorans* forms isobutyrate + acetate from isobutanol (Hermann et al., 1987).

Ecology

The distribution of *Sporomusa* in anoxic habitats seems to be fairly wide. However, our understanding of their ecology is still fragmentary. Like that of other H_2/CO_2-utilizing homoacetogens, their threshold for H_2 is relatively high (430 and 830 parts per million by volume (ppmv) for *S. acidovorans* and *S. termitida*, respectively; Cord-Ruwisch et al., 1988), implying that they are unlikely to be effective competitors for H_2 in the presence of H_2-utilizing methanogens, sulfidogens or denitrifiers. Rather, it would appear to be their ability as a group to use a wide range of substrates that may grant them significant membership in decomposer communities, augmented by their ability to utilize H_2 chemoautotrophically, or mixotrophically (Breznak and Blum, 1991), when competition for this substrate is not severe. Hence, a more likely role for them in

anaerobic microbial communities is as ferment-
ers of small molecules, partnering with methano-
gens and/or sulfidogens through interspecies
transfer of H_2. Indeed, by interspecies transfer of
H_2 during growth on methanol, *Sporomusa* could
support the growth of H_2-consuming methano-
gens and sulfidogens unable to use methanol on
their own (Cord-Ruwisch and Ollivier, 1986;
Heijthuijsen and Hansen, 1986; Hermann et al.,
1987). Under such conditions, a greater fraction
of the methanol was completely oxidized to CO_2
by the *Sporomusa* and proportionally less (or
no) acetate was formed by the coculture. Inter-
species transfer of H_2 to methanogens has also
been observed for *S. paucivorans* during glycerol
fermentation (Hermann et al., 1987). As H_2-
utilizing strains of *Sporomusa* also produce a
small amount of formate during chemoauto-
totrophic growth, interspecies transfer of for-
mate is also possible (Peters et al., 1999).
Syntrophic utilization of organic substrates with
methanogens and sulfidogens may account for
the significant populations of *Sporomusa* in rice
paddy soils (nearly 10^9 cells per g dry soil; Rosen-
crantz et al., 1999) and lake sediments (ca. 105
cells/ml; Sass et al., 1997; Sass et al., 1998).

   Sporomusa also can be found in habitats that
are not strictly, or entirely, anoxic. For example,
S. silvacetica was isolated from well-drained,
aggregated forest soil, a habitat subject to fluctu-
ations in aeration and redox potential. Presum-
ably, its microhabitat in soil consists of anoxic or
microoxic pockets present in soil crumbs (Kuh-
ner et al., 1997). Preliminary studies of the O_2
tolerance of *S. silvacetica* and other homoaceto-
gens revealed that 0.5–1% O_2 in the gas phase of
non-chemically-reduced media had little or no
effect on growth rates or biomass yield. The O_2
was consumed by the acetogens under such con-
ditons, although it is not yet known whether such
O_2 consumption is coupled to energy conserva-
tion (Karnholz et al., 2000). The tolerance to O_2
of *S. silvacetica* and other homoacetogens helps
account for the H_2-consuming, acetogenic capac-
ity of soils (see Kuhner et al., 1997, and refer-
ences therein). Similarly, *S. termitida* was isolated
from hindguts of wood-eating termites, another
habitat consisting of oxic and anoxic zones
(Brune et al., 1995; Ebert and Brune, 1997),
wherein it was felt to contribute to acetogenesis
from H_2+CO_2 and, hence, termite nutrition
(Breznak et al., 1988; Breznak, 1994a).

   Recognition of the wide distribution of *Sporo-
musa*, and the current availability of 16S rRNA
sequences of representatives of all known spe-
cies of the genus, will hopefully prompt a more
comprehensive examination of the ecology of
this group of bacteria, an effort that should be
facilitated by the use of rRNA sequence-based
molecular tools.

CHAPTER 1.3.5

The Family Lachnospiraceae, Including the Genera *Butyrivibrio*, *Lachnospira* and *Roseburia*

MICHAEL COTTA AND ROBERT FORSTER

Butyrivibrio

Introduction

Members of the genus *Butyrivibrio* are non-spore forming, anaerobic, motile, curved rod-shaped bacteria that are commonly isolated from the gastrointestinal tract of mammals. The Gram-negative staining of these organisms in no way reflects the true nature of the cell wall structure. Chemical and electron microscopic analyses of *Butyrivibrio* cells have revealed a thin, Gram-positive ultrastructure (Cheng and Costerton, 1977; Hespell et al., 1993). The genus is composed of two species, *B. fibrisolvens* and *B. crossotus*. Ruminal butyrivibrios characteristically produce butyric acid and degrade plant fibers such as xylans. Hence, the name *Butyrivibrio fibrisolvens* is quite descriptive (Bryant and Small, 1956a). *Butyrivibrio* strains isolated from human fecal material differ in substrate utilization and flagellar arrangement from *B. fibrisolvens*. These strains have been designated as *B. crossotus* to reflect the presence of "tasseled," multiple flagella (Moore et al., 1976). Phylogenetic (DNA–DNA hybridization and 16S rDNA gene sequence) analyses indicate *B. fibrisolvens* strains are a genetically heterologous group of organisms, likely comprised of several species and numerous unrelated strains (Table 1; Mannarelli, 1988; Forster et al., 1996; Mannarelli et al., 1990b; Willems et al., 1995). However, these strains obviously have enough phenotypic similarities to be used to presumptively identify new isolates as *B. fibrisolvens*. These findings are not entirely surprising as it has been known for some time that *B. fibrisolvens* strains differ greatly in serological properties (Margherita and Hungate, 1963; Margherita et al., 1964; Hazlewood, et al., 1986) and in nutritional properties (Bryant and Small, 1956a; Bryant and Robinson, 1962).

Phylogeny

The *Butyrivibrio* are phylogenetically placed within Cluster XIVa of the *Clostridium* subphy-lum, as defined by Collins et al., 1994. Cluster XIVa contains a diverse array of Gram-positive bacteria including members of the *Clostridium*, *Coprococcus*, *Lachnospira*, *Eubacterium*, *Ruminococcus*, *Syntrophococcus*, *Roseburia* and "*Acetitomaculum*." The *Butyrivibrio* belong to three phylogenetically distinct groups (Fig. 1) within this cluster (Forster et al., 1996; Willems et al., 1995). Although the majority of the *Butyrivibrio* will stain Gram-negative, the phylogenetic placement of the group among the low mol% GC content Gram-positive bacteria supports studies that demonstrated a Gram-positive type cell wall structure (Cheng and Costerton, 1977; Hespell et al., 1993).

The strains of *B. fibrisolvens* designated to be in group I are those strains that cluster with the type strain, D1 (ATCC 19171). The strains within this group have 16S rDNA similarities of ≥92% and include the recently described *C. proteoclasticum* (Attwood et al., 1998). Strains clustering in group II have similarities of ≥96% and include *Pseudobutyrivibrio ruminis*. A distinct subgroup consisting of strains OB189, OB156, OB157 and OB192 appears in Group II (designated group IIb). All of the strains in this subgroup were isolated from the rumen of a wild white-tailed deer and have not been detected in significant numbers in domesticated ruminants. Similarities between groups I and II range from 86.8% to 89.9%. *B. crossotus* (group III) has similarities to groups I and II of approximately 90%. There are more than 31 distinct rRNA types within the *Butyrivibrio* (Table 1), and this number will increase as the 16S rDNA sequence of more strains are determined. The levels of rRNA similarity within and between the groups of *Butyrivibrio* indicate that many of these strains, especially those within group I, represent different species within the *Butyrivibrio* genus, and that groups II and III could be considered to be genera in their own right.

In general, the 16S rRNA phylogenetic analysis of the *Butyrivibrio* have supported the DNA:DNA homology analysis of (Mannarelli, 1988) and (Mannarelli, et al., 1990b). However, there are four *Butyrivibrio* strains for which

[a]Strains listed on the same line or with the same number designation have at least 99.4% 16S rRNA similarity.
[b]Mannarelli et al., 1990b.
[c]Willems et al., 1996.

these analyses disagree. The 16S rRNA sequence of strain B835 (NCDO 2398) was initially determined to be related to group I *Butyrivibrios* (Willems et al., 1995), but the DNA:DNA determinations of Mannarelli, 1988 indicated it was closely related to NOR37 and the group II butyrivibrios. Recently Diez-Gonzalez et al., 1999 determined the 16S rRNA sequence of strain B835 used by Mannarelli, 1988 and found that it was indeed closely related to NOR37. The authors suggest that two unrelated isolates have the same B835 strain designation. The results of (Mannarelli et al., 1990b) also indicate that strains VV1–VV5 cluster within the *B. crossotus* DNA homology group 6. However, 16S rRNA data indicate that strain VV1 has an identical 5' 16S rDNA sequence to the group II strains Bu49, H17c and UC12254 (R.J. Forster, unpublished ovservation). Some confusion also may exist between strains LM8/1B and M3.8 because the 16S rRNA-based phylogeny places these strains in group I and II, respectively, whereas the DNA:DNA homology analysis produces the opposite result. Strains LM8/1B, M3.8 and the VV1–VV5 strains will need to be reexamined to resolve these inconsistencies.

As discussed throughout this chapter, the *Butyrivibrio* are a heterofermentative group of bacteria. When examined together, the fermentation patterns of the various strains of *Butyriv-*
Fig. 1. Phylogenetic tree for *Butyrivibrio*, *Lachnospira*, *Roseburia* and related bacteria. The tree was reconstructed using a neighbor-joining method and the two-parameter model of Kimura as implemented in the PHYLO-WIN program (Galtier et al., 1996). Bootstrap values above 90% are indicated at the branch points, expressed as the percentage from 1000 resampled trees.

ibrio do not follow a phylogenetically coherent pattern. Differentiating *Butyrivibrio* strains on a phenotypic basis has been problematic. This is exemplified by the description of *Pseudobutyrivibrio ruminis* (van Gylswyk et al., 1996) as a bacterium that is non-xylanolytic, non-amylolytic and non-proteolytic. The description of this genus was based on a single isolate, without comparison to the broad range of *Butyrivibrio* strains in current culture collections. Indeed, strains of *B. fibrisolvens* such as CF3 and OR35, which share greater than 99% 16S rRNA sequence homology to *P. ruminis*, are highly xylanolytic, ferment starch and may or may not hydrolyze gelatin. The description of *Pseudobutyrivibrio* thus is not consistent with the phylogenetic classification of the group II *Butyrivibrio*. The observation that butyrate kinase activity is present in group I strains and is absent in group II strains, and conversely that butyryl CoA/acetyl CoA transferase is absent in group I strains and present in group II strains (Diez-Gonzalez et al.,

1999), may lead to a phylogenetically and phenotypically accurate description of these two groups. More strains will need to be examined to determine if these different patterns of butyrate production are indeed consistent between the two main groups of *Butyrivibrio*.

Habitat

Butyrivibrio spp. are common inhabitants of the rumina of cattle and other ruminants (e.g., sheep, goats, reindeer) where they are generally among the more numerous bacterial species present under a variety of different feeding regimes (Stewart and Bryant, 1988; Varel and Dehority, 1989; Dehority, 1986; Dehority and Grubb, 1977; Orpin et al., 1985; Olsen et al., 1997). They also are found in the cecal and fecal contents collected from these animals (Mathieson et al., 1987; Lewis and Dehority, 1985). In addition to ruminants, *Butyrivibrio* spp. are also present in the gastrointestinal tract of a variety of other

mammals and have been isolated from feces or cecal contents of rabbits, horses, humans and swine (Brown and Moore, 1960; Moore et al., 1987; Rumney et al., 1995). *Butyrivibrio* spp. have been isolated from animals in numerous geographical areas throughout the world. It also should be noted that butyrivibrios can occur in environments outside of animals, and strains have been isolated from Napier grass-fed anaerobic digestors (Sewell et al., 1988).

Isolation

BUTYRIVIBRIO FIBRISOLVENS *Butyrivibrio fibrisolvens* strains are extremely versatile and have been isolated using a variety of culture media and growth conditions, however, no definitive selective isolation or enrichment procedures have been published. Strains of *B. fibrisolvens* and *Prevotella ruminicola* are the predominant isolates obtained from ruminal contents when xylan is the only added carbohydrate source provided in the isolation medium (Dehority, 1966; Van der Toorn et al., 1985). *Butyrivibrio* strains also are frequently isolated from ruminal (Shane et al., 1969) or cecal (Lewis and Dehority, 1985) contents when media containing ball-milled or finely ground cellulose are used. With these cellulose-containing media, colonies of butyrivibrios often are surrounded by weak zones of cellulose degradation compared to the extensive clearing produced by cellulolytic cocci (e.g., *Ruminococcus* species) or by nonmotile, pleomorphic rods (e.g., *Fibrobacter succinogenes*). *Prevotella* and *Butyrivibrio* strains constitute the majority of bacterial isolates obtained from ruminal contents when media containing plant saponins are used (Gutierrez et al., 1959). *B. fibrisolvens* strains are resistant to high levels (30 to 500 μg per ml) of nalidixic acid (Hespell et al., 1993), but most strains are quite sensitive to many antibiotics, especially those that affect cell wall synthesis (e.g., penicillin, bacitracin; Fulghum et al., 1968; Hespell et al., 1993). Since all well-characterized *B. fibrisolvens* are uniformly xylanolytic, a selective medium for *B. fibrisolvens* strains might be constructed with xylan as the sole carbohydrate source and nalidixic acid.

BUTYRIVIBRIO CROSSOTUS *B. crossotus* has been isolated from human fecal and rectal contents using nonselective, rumen fluid-glucose-cellobiose medium (Holdeman et al., 1976; Moore et al., 1976). More selective isolation media or enrichment procedures for this species are not known. Although *B. crossotus* is less versatile than *B. fibrisolvens*, the type strain of this species is also resistant to nalidixic acid, which may prove useful in the construction of selective media for this organism (Hespell et al., 1993).

Identification

BUTYRIVIBRIO FIBRISOLVENS Many *B. fibrisolvens* strains produce surface colonies that are 2 to 4 mm in diameter, entire, slightly convex, translucent, and light tan to white in color, when grown on complex carbohydrate agar-containing media (Bryant and Small, 1956a; Bryant, 1986a). Some strains produce rough colonies that have filamentous edges and might represent strains that produce little extracellular polysaccharide material. In contrast, strains such as the CF types produce large amounts of extracellular polysaccharide, the colonies are quite mucoid and, gas bubbles can be seen to emanate from the colonies. Subsurface colonies of most strains are lenticular to "Y" shaped, and double lens-shaped colonies are not uncommon. In cellulose-containing media, the cellulose-digesting strains are surrounded by a zone of cellulose degradation, variable both in zone size and extent of digestion (usually weak). Similar observations also occur when media containing natural xylans are used. However, if a dyed xylan (e.g., Remazol brilliant blue xylan) is used, large clear zones surround the colonies of all strains. Most strains grow rapidly in broth cultures and produce flocculent sediment, whereas some strains produce granular sediment that adheres to glass surfaces. Cultures of these latter strains and those that produce large amounts of extracellular polysaccharides can become quite thick and viscous when the media contain large amounts (≥0.5%) of the energy source.

The classical appearance of *B. fibrisolvens* is a small, motile, slightly curved rod (0.4 to 0.6 mm × 2 to 5 mm long) with tapered and rounded ends (Fig. 2A, B). However, there is considerable variation amongst strains. The cells of some strains are almost spindle-shaped, while cells of other strains are quite curved and can form helices composed of two to four cells.

The cells show translational motility characterized by rapid or intense vibrating movement. Motility is by means of monotrichous flagellation, with the flagellum attached subterminally. Although often only a few cells in a wet mount preparation may show motility, truly nonmotile strains have not been well documented. The lack of motility in an isolated strain is often due to cultural conditions employed. Bryant and Small, 1956a reported that 15 strains were nonmotile when grown in a ruminal fluid-glucose-cellobiose medium, but all were motile if cellobiose was deleted and the glucose concentration decreased. Growth of most strains is rapid (doubling times of 2 h or less) and much acid production occurs. Low pH due to acid production may inhibit motility and also inhibits growth (Gill and King, 1958; Russell and Dombrowski, 1980;
Fig. 2. Electron micrographs of *B. fibrisolvens* 113. (A) Whole cell, platinum-shadowed. Bar = 0.5 μm. (B) Thin section of cells, showing filamentous aspects of attached cells after cross-wall formation. Bar = 1.0 μm. (From Sewell et al., 1988.)

Therion et al., 1982). Because of these effects, cell characteristics and motility should be monitored in young cultures and in media with a low amount of added energy source.

The initial study of *Butyrivibrio* (Bryant and Small, 1956a) and many subsequent studies (Brown and Moore, 1960; Cheng et al., 1969; Shane et al., 1969; Sewell et al., 1988) have consistently reported that *Butyrivibrio* strains appear as Gram-negative cells when stained by conventional procedures and viewed by light microscopy. However, *B. fibrisolvens* strains 49, NOR37, and 1L631 were found to possess lipoteichoic acids, which are present only in Gram-positive bacteria (Sharpe et al., 1975; Hewett, et al., 1976). Later, Cheng and Costerton, 1977 established by electron microscopic observations that *B. fibrisolvens* strain D1 had a Gram-positive cell wall structure. The peptidoglycan layer, however, was very thin (12 to 15 nm) compared to normal Gram-positive bacteria (30 to 50 nm), and it was thought that the Gram-negative staining of *Butyrivibrio* sp. might be based on the thinness of the peptidoglycan. A comprehensive examination of the peptidoglycans from strains of *B. fibrisolvens* (Hespell et al., 1993) indicate the peptidoglycans are of similar composition and low degree of crosslinking: a modified meso-diaminopimelic acid direct-link peptidoglycan as described by Schleifer and Kandler, 1972. Cell wall preparations also contained unusually high concentrations of glucosamine. Electron microscopic examination of cells in this study also confirmed the Gram-positive nature of *Butyrivibrio* cell walls. Consistent with this cell wall type, all *B. fibrisolvens* are quite sensitive to penicillin or bacitracin, but all are resistant to nalidixic acid.

In contrast to many other species of ruminal bacteria, any given *B. fibrisolvens* strain is capable of fermenting a wide variety of carbohydrates. All strains are xylanolytic. The majority of strains ferment starch and pectin. Some strains weakly degrade cellulose. Though it was thought that degradation of rutin was a common trait in *B. fibrisolvens* strains (Hespell and Bryant, 1981), this property is found in only a few strains. Almost all strains can ferment 15 to 20 different soluble carbohydrates and the most commonly used ones include glucose, maltose, sucrose, fructose, cellobiose, xylose, and arabinose. With respect to nitrogen requirements, ammonia can serve as the sole nitrogen source for most *B. fibrisolvens* strains (Bryant and Robinson, 1962). Many strains also can use mixtures of amino acids or more complex nitrogen sources (trypticase, casein hydrolysate, peptone). However, ammonia supports considerably more growth than an equivalent amount of peptide or amino acid nitrogen when these compounds are provided at growth-limiting concentrations (Bryant, 1973). When measured by gelatin liquefaction, many strains appear nonproteolytic. This is probably a misleading conclusion, particularly if high levels (e.g., 10 to 12%) of gelatin are used in the medium for determining activity. A survey of a large number of strains indicated they are proteolytic when this activity is measured by azocasein hydrolysis (Cotta and Hespell, 1986). In fact, constitutive production of protease as well as esterase and lipase (Hespell and O'Bryan-Shah, 1988) activities appears to be very common traits in *B. fibrisolvens* strains.

Butyrivibrio fibrisolvens strains produce large amounts of n-butyric acid during the fermenta-

tion of carbohydrates. Smaller amounts of formate and hydrogen gas also are made by all strains. Many strains produce trace amounts of ethanol, but no strain produces succinate. Although some strains require carbon dioxide to initiate growth, all studied strains produce carbon dioxide (Dehority, 1971). *B. fibrisolvens* strains generally exhibit two major fermentation acid patterns. One type produces large amounts of lactate and removes acetate added to the medium, while the other type produces little or no lactate but substantial amounts of acetate. These fermentation patterns have been used to separate butyrivibrio-like isolates (Shane et al., 1969). Hungate, 1966 proposed another species, *B. alactacidigens*, for those strains that do not produce lactate. More recently, Diez-Gonzalez et al., 1999 found that these phenotypes could be explained by the mechanism of butyrate production used by strains. Acetate utilizing-lactate producing strains (like strain 49) possessed butyryl CoA/ acetylCoA transferase activity, while acetate producing strains (like strain D) used butyrate kinase to produce butyric acid. The presence and absence of these activities in the strains examined were consistent with phylogenetic groupings based on 16S rDNA sequence analyses and may serve as a valuable taxonomic marker.

The production of large amounts of n-butyric acid from the fermentation of carbohydrates, along with cell morphology and Gram-staining, are characteristics that can be used to place a newly isolated strain into the species *B. fibrisolvens* While it seems reasonable that *B. fibrisolvens* strains could be separated on the basis of specific carbohydrate usage into groups that would be consistent with genetic groups (Table 1), sufficient information is not yet available to create this determinative classification. At present, a useful phenotypic trait that allows for placement of newly isolated butyrivibrio-like strains into one of these DNA relatedness groups is neutral sugar composition of the extracellular polysaccharides. These polysaccharides are easily isolated from culture fluids and can be analyzed by well-established techniques (Stack, 1987; Stack, 1988a).

BUTYRIVIBRIO CROSSOTUS In addition to *B. fibrisolvens*, the only other species presently in this genus is *Butyrivibrio crossotus*. This species can be isolated from human rectal or fecal material and differs considerably from *B. fibrisolvens* (Moore et al., 1976). Strains of this bacterium are motile by means of polar to subpolar, lophotrichous flagella. Surface colonies on brain heart infusion agar are quite small (0.2 to 1.0 mm diameter), circular, convex, and translucent. Slightly larger subsurface colonies are produced

and are lenticular in shape. The cell morphology is similar to *B. fibrisolvens* and cells stain Gramnegative. *B. crossotus* has a narrow range of fermentable substrates that include maltose, starch, glycogen, and dextrin. Large amounts of butyrate are made and some hydrogen gas is formed by most strains. Tests for lecithinase, lipase, and ammonia production from peptone are negative. As pointed out by Moore and Holdeman, 1974, *Eubacterium rectale* is part of the normal human fecal flora and many strains are very similar to *Butyrivibrios*.

Cultivation

Members of *Butyrivibrio* are all strictly anaerobic bacteria and appropriate steps should be employed to remove and exclude oxygen from growth medium (e.g., use of the technique of Hungate and modified by Bryant, 1972). The complex, Routine Growth Medium (RGM, Table 2) can be used to grow strains of these bacteria as well as many other species of ruminal bacteria (Hespell et al., 1987). These bacteria can be grown at 37°C, but usually little or no growth takes place at 30 or 45°C. Many *B. fibrisolvens* strains are not nutritionally fastidious and can be grown on a chemically defined medium (Table 2), which has been used in studies of proteolytic activities with these strains (Cotta and Hespell, 1986). Most *B. fibrisolvens* strains can use ammonia as a sole nitrogen source and many strains also can use urea. Peptides in the form of trypticase or other peptones are not required, but often stimulate growth when added to ammonia-containing media (Bryant and Robinson, 1962). The precise vitamin and other growth requirements for most strains of Butyrivibrio have not been determined.

Preservation

Most strains of *Butyrivibrio* can be maintained for long times by storage of cultures in liquid nitrogen or in ultracold freezers (Hespell and Canale-Parola, 1970). Preservation by lyophilization under anaerobic conditions may be possible, and strains obtained from culture collections are provided in this form. Short-term storage (6 to 15 months) is possible by placing glycerol-containing cultures in normal (–20°C) freezers (Teather, 1982a).

Physiology

Butyrivibrio fibrisolvens is quite versatile in the polymeric substrates that it can metabolize, and cellulolytic, xylanolytic, amylolytic, and pectinolytic strains have been isolated. While all characterized strains of *B. fibrisolvens* are highly

[d]Prepared, autoclaved, and stored under a nitrogen gas phase.
[e]Containing per 100ml N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid buffer (5mM; pH 7.5): biotin, folic acid, Δ-aminobenzoic acid, and cyanocobalamin (2.5mg each); calcium pantothenate, nicotinamide, riboflavin, thiamine hydrochloride, and pyridoxamine (20mg each). The resulting solution is filter sterilized (pore size, 0.22μm) and stored under nitrogen in a dark container.
[f]Prepared by adding 7-ml acetate, 3-ml propionate, 2-ml butyrate, and 0.6-ml each of isobutyrate, 2-methyl-butyrate, isovalerate, and n-valerate to 700ml of 0.2M NaOH. Adjust to pH 7.0 with NaOH and to final volume of 11.
[g]Mineral A = 0.5% K_2HPO_4.
[h]Mineral B = 1.0% KH_2PO_4, 1.2% NaCl, 0.58% $NaSO_4$, 0.16% $CaCl_2X2H_2O$, and 0.25% $MgSO_4X7h_2O$.
[i]Prepared as described by Hespell and Canale-Parola (1970) by adding 25ml of modified Pfennig's metals to 3.75g $CaCl_2X2H_2O$, 12.5g $MgCl_2X6H_2O$, 0.5g $FeSO_4X7H_2O$, and 1.0g Na_4EDTA dissolved in 75ml distilled water. Modified Pfennig's metals are prepared by separately dissolving (heat if needed) each of the following compounds in distilled water and adding (in order) to 11 distilled water: 0.5g $AlCl_3$, 0.25g KI, 0.25g KBr, 0.25g LiCl, 3.5g $MnCl_2X4H_2O$, 5.5g H_3BO_3, 0.5g $ZnCl_2$, 0.5g $CuCl_2X2H_2O$, 0.5g $NiCl_2X6H_2O$, 0.5g $CoCl_2X6H_2O$, 0.15g $SnCl_2X2H_2O$, 0.15g $BaCl_2X2H_2O$, 0.25g $NaMoO_4X2H_2O$, and 0.05g $NaVO_3$. The resultant solution is adjusted to pH 3.0 to 4.0 with HCl and brought to a final volume of 1.81 with distilled water.
[j]Made by dissolving 25mg 1.4-naphthoquinone in 2ml 95% ethanol, adding 48ml distilled water and 10mg hemin dissolved in 50ml of 0.01M NaOH.
[k]Autoclaved separately; prepared, equilibrated, and stored under a carbon dioxide gas phase.

xylanolytic, only about 10% of these strains are capable of good growth on cellulose. A few strains are capable of anaerobically degrading complex heterocyclic compounds of the bioflavonoid type (Cheng et al., 1969; Cheng et al., 1970). Some strains can deacetylate trichothecenes such as T-2 toxin (Westlake et al., 1987). *B. fibrisolvens* is active in the biohydrogenation of fatty acids in the rumen (Harfoot and Hazlewood, 1988) and strains producing phospholipase and galactolipase have been identified (Hazlewood, et al., 1983).

Because of its role in the digestion and metabolism of hemicellulose (xylan) in the rumen, much research has focussed on the xylanolytic activity of *B. fibrisolvens*. Xylan is a complex polysaccharide contained in plant cell walls and is composed of a β 1,4-linked xylose backbone with side groups of arabinose, uronic acids, and other sugars. The xylose residues are also frequently acetylated. As a result, several enzymatic activities are required to hydrolyze this polysaccharide to monosaccharides. *B. fibrisolvens* strains have been identified that produce endo-xylanase, β-xylosidase, arabinofuranosidase, cinnamoyl esterase and acetylxylan esterase (Hespell and O'Bryan-Shah, 1988; Hespell and Whitehead, 1990; Williams and Withers, 1992a; Williams and Withers, 1992b; Lin and Thomson, 1991a; Hespell et al., 1987; Akin et al., 1993). In some cases the genes responsible for these activities have been cloned and analyzed and the proteins purified and characterized (Dalrymple et al., 1996; Thompson, 1993; Sewell et al., 1989; Hespell and O'Bryan, 1992; Utt et al., 1991; Lin and Thomson, 1991b; Mannarelli et al., 1990a; Dalrymple and Swadling, 1997). The production of xylanolytic enzymes is regulated in strains that have been examined. Some evidence exists that these enzymes may be in a large molecular weight assemblage containing a variety of extracellular enzyme activities. *B. fibrisolvens*

also produces amylase, endo-glucanase, pectin esterase, and exopectin lyase activities also important in the digestion and metabolism of plant polysaccharides (Thompson, 1993; Hazlewood et al., 1990; Heinrichova et al., 1985; Wojciechowicz et al., 1982; Cotta, 1988; Rumbak et al., 1991).

Most strains are proteolytic and produce protease activity equal to or greater than that found with other proteolytic ruminal bacteria such as *Ruminobacter amylophilus* or *Prevotella ruminicola* (Cotta and Hespell, 1986; Wallace and Brammall, 1985; Strydom et al., 1986). The most active strains appear to produce extracellular proteolytic activity of the serine protease type. Some low activity strains producing cell-associated, cysteine protease-like activities also have been identified. Regulation of protease activity has not been studied extensively. In strain 49, the activity is constitutively produced, but growth parameters and the availability of complex nitrogen sources modulate the level of activity (Cotta and Hespell, 1986). *B. fibrisolvens* produces peptidases and produces ammonia from peptides and amino acids (Wallace and McKain, 1991; Bladen et al., 1961; Scheifinger et al., 1976). Glutamate dehydrogenase and glutamine sythetase (type GS III) activities have been detected in *B. fibrisolvens* (Goodman and Woods, 1993; Joyner and Baldwin, 1966). Some strains are ureolytic (Wozny et al., 1977). Little is known about control of these activities.

B. fibrisolvens strains ferment a wide array of hexoses and pentoses, and the utilization of carbohydrates is regulated. Although not examined for many strains, substrate utilization patterns suggest the involvement of catabolite regulatory mechanisms (Russell and Baldwin, 1978). However, evidence for the involvement of cAMP or regulatory elements of the phosphoenol pyruvate, phosphotransferase systems is lacking (Cotta et al., 1994; Strobel, 1994; Martin and Russell, 1986). *B. fibrisolvens* strains characteristically produce butyric acid as the main product from fermentation of carbohydrates (Bryant and Small, 1956a; Hespell et al., 1987). The formation of the other fermentation acids varies considerably, depending upon the strain. Shane et al., 1969 subdivided strains of *Butyrivibrio* into two groups. Group 1 strains utilized acetate and made small amounts of formate and large amounts of lactate. Group 2 strains produced acetate and made large amounts of formate and small amounts of lactate. This phenotypic difference is not always clear-cut and can be influenced by culture conditions. Utilization of acetate is stimulated by low availability of carbon dioxide, presence of lactate, and growth-limitation of energy source (Latham and Legakis, 1976; Jarvis et al., 1978). In addition, acetate utilization is affected by the levels of acetate added to the medium as well as by the growth rate of the culture. The levels of acetate can markedly affect the production of lactate by certain strains. The utilized acetate is primarily incorporated into butyrate on almost an equal molar basis with acetate formed from the fermented carbohydrate source.

Biochemical and enzymatic studies with *B. fibrisolvens* have not been extensive. The key enzymes of the Embden-Meyerhof pathway plus lactate dehydrogenase, phosphotransacetylase, and acetate kinase have been detected at high levels (Joyner and Baldwin, 1966; Kistner and Kotze, 1973; Kotze and Kistner, 1974). Based on studies employing radiolabeled substrates, pyruvate synthase and pyruvate-formate lyase activities are present in *B. fibrisolvens* (van Gylswyk, 1976). The formation of butyryl-CoA from acetyl-CoA involves the sequential actions of thiolase, β-hydroxy butyryl-CoA dehydrogenase, crotonase, and crotonyl-CoA reductase (Miller and Jensel, 1979). Butyryl-CoA is converted to butyrate by phosphotransbutyrylase and butyrate kinase or via butyryl CoA/acetyl CoA transferase reactions (Diez-Gonzalez et al., 1999). In regard to biosynthetic metabolism, oxaloacetate is formed by the action of phosphoenolpyruvate carboxykinase (van Gylswyk, 1979). Glutamate, succinate, malate, and isocitrate dehydrogenases appear to be present (Joyner and Baldwin, 1966).

Genetics

The isolation of a large, 200-kDa plasmid from *B. fibrisolvens* (Teather, 1982b) was the first demonstration that strains of *Butyrivibrio* contained extrachromosomal elements. A search for smaller plasmids that could prove useful for the development of genetic transformation systems resulted in the isolation of a 2.8-kb plasmid, pOM1, from *B. fibrisolvens* 49 (Mann et al., 1986). An additional native plasmid, pBF1, was cloned and characterized from *B. fibrisolvens* AR10 (Ware et al., 1992). The first full sequence of a plasmid from a rumen bacterium was obtained from *B. fibrisolvens* OB156 (Hefford et al., 1993). The plasmid, pRJF1, was determined to be 2.6 kb and contained a complex series of direct and inverted repeats, reminiscent of theta-replication regions of other Gram-positive plasmids. The plasmid encoded two open reading frames (ORF's), which had limited homology to known sequences, and a unique *Hind*III site within a noncoding stretch of DNA bounded by a 79-bp inverted repeat. This unique *Hind*III site was later used to combine the *E. coli* vector pUC118 and an erythromycin resistance gene from pAMβ1 with pRJF1, to produce a stable

rumen bacterial shuttle vector (pBHerm) to transform *B. fibrisolvens* by electroporation (Beard et al., 1995).

In a further effort to develop transformation systems, pOM1 was sequenced, and a stable shuttle vector (pSMerm) developed by combining the same *E. coli* replication elements and erythromycin-resistance gene introduced into pRJF1 (Hefford et al., 1997). Plasmid pOM1 was determined to replicate by a rolling circle mechanism, and pSMerm could be transformed simultaneously into *B. fibrisolvens* OB156 with pBHerm. An additional plasmid transformation system has been developed using pUC18 and pAMβ1 with the native plasmid pRJF2 (Kobayashi et al., 1995), isolated from *B. fibrisolvens* OB 157. Plasmids pRJF1 and pRJF2 are highly homologous, and differ mainly in sequence and length in the noncoding region between the conserved 79-bp repeats. Optimal electroporation conditions for these plasmids have been published (Kobayashi et al., 1997).

The first successful introduction of plasmid DNA into *B. fibrisolvens* was accomplished by conjugation using the transposon Tn*916* and the self-mobilizing plasmid pAMβ1 (Hespell and Whitehead, 1991). Subsequently, conjugation with pUB110 from *S. aureus* (Clark et al., 1994) into *Butyrivibrio* was also achieved. Stable transformation of *B. fibrisolvens* also has been demonstrated using electroporation with the *E. coli/B. subtilis* shuttle vector pBS42 (Whitehead, 1992). Although a number of *Butyrivibrio* strains have been successfully transformed with the systems described above, the majority of strains are resistant to transformation by electroporation. Restriction-modification systems have been characterized in *Butyrivibrio* (Mohn and Teather, 1995) and may account for this lack of success.

A number of genes cloned from strains of *B. fibrisolvens* play a role in polysaccharide degradation. These genes include an endoglucanase (*endI*) from H17c (Berger et al., 1990), a β-D-xylosidase/α-L-arabinofuranosidase (*xylB*) from GS113 (Sewell et al., 1989), a xylanase (*xynA*) from strain 49 (Mannarelli et al., 1990a), an endoglucanase (*celA*) from A46 (Hazlewood et al., 1990), a β-glucosidase (*bglA*; Lin et al., 1990), cellodextrinase (*cedI*; Berger et al., 1990), and a xylanase (*xynB*; Lin and Thomson, 1991b) from strain H17c as well as two cinnamoyl ester hydrolases (*cinA* and *cinB*) from strain E14 (Dalrymple et al., 1996; Dalrymple and Swadling, 1997). An investigation of the distribution and evolutionary relationships of the *xynA* and *xynB* genes from *Butyrivibrio* revealed that the *xynB* gene was present in three of the seven group I *Butyrivibrio* strains examined (Dalrymple et al., 1999). However the *xynA* gene was found to con-

sist of two subfamilies, each of which was present in group I and group II strains. It was noted that 5 of the 6 best xylan-degrading strains of *Butyrivibrio* contained a member of *xynA* subfamily A.

The expression and secretion of an introduced fungal xylanase in *B. fibrisolvens* OB156 was improved by manipulating promoter sequences (Xue et al., 1997). Successful expression of the xylanase was found with a promoter sequence from *B. fibrisolvens* strain 49 but strain OB156 did not efficiently recognize E. coli promoter sequences. The secretion of the xylanase also was improved significantly when a signal sequence from *B. fibrisolvens* H17c was manipulated to increase its hydrophobicity. Further increases in the efficiency of gene expression in *Butyrivibrio* will be dependent upon detailed analysis of *Butyrivibrio* promoter sequences. Recently a promoter-rescue plasmid for *B. fibrisolvens* has been described (Beard et al., in press), which will aid in this important area of research.

Other genes cloned from *B. fibrisolvens* H17c include an α-amylase (*amyA*) (Rumbak et al., 1991a), a 1,4-α-glycosyltransferase (*glgB*; Rumbak et al., 1991b) and a glutamine synthase gene (Goodman and Woods, 1993). The structural gene (*bvi79A*) encoding a bacteriocin from *B. fibrisolvens* strain OR79 was cloned and characterized (Kalmokoff et al., 1999). Along with the bacteriocin encoding gene, the cloned fragment was found to contain 4 other ORFs with significant homology to genes involved in antibiotic production or immunity. The bacteriocin gene encoded a prepeptide of 47 amino acids and was processed into a mature bacteriocin of 25 amino acids.

Ecology

Butyrivibrio fibrisolvens strains are invariably found in the rumen of animals fed a wide range of diets, but these bacteria usually are in considerable numbers with animals fed diets high in forage materials that are generally poorly digested (Thorley et al., 1968; Shane et al., 1969). All *B. fibrisolvens* strains attack the hemicellulose (xylan) portion of plant cell walls, and many also can hydrolyze other plant polysaccharides like starch and pectin (Hespell et al., 1987). Some strains also can degrade cellulose. Most strains are proteolytic (Cotta and Hespell, 1986). *Butyrivibrio* strains have been identified that are active in specialized activities that occur in the rumen including fatty acid biohydrogenation, bioflavanoid degradation (e.g., rutin), and mycotoxin modifications (Harfoot and Hazlewood, 1988; Westlake et al., 1987; Cheng et al., 1969). Given this wide biochemical diversity of *Butyrivibrio* strains, these bacteria are involved in many important ecological roles in the rumen

and probably also in the cecum and large intestine of many mammals.

Although not as effective at fiber digestion as species of *Ruminococcus* or *Fibrobacter*, many *Butyrivibrio* strains are capable of solubilizing about 20–45% of the entire plant cell wall (Morris and van Gylswyk, 1980). During the degradation of xylan, solubilization occurs at a faster rate than utilization of the breakdown products (Dehority, 1967). In pure culture, these breakdown products have been identified as xylooligosaccharides and can serve as substrates for the growth of non-xylanolytic, oligosaccharide-fermenting bacteria (Cotta and Zeltwanger, 1995; Hespell and Cotta, 1995). A similar phenomenon has been demonstrated for the degradation of starch by *B. fibrisolvens* (Cotta, 1992). Improved utilization of polysaccharides can be observed when *B. fibrisolvens* is cocultivated with other ruminal bacteria, but synergistic attack on polysaccharides was not apparent. Such cross feeding between polysaccharide-hydrolyzing and simple sugar-fermenting species are thought to be an important ecological interaction among species present in the rumen environment.

B. fibrisolvens is one of the most numerous protein-degrading species of bacteria isolated from the rumina of animals on various diets (Blackburn and Hobson, 1962; Fulghum and Moore, 1963; Hazlewood et al., 1983). Most strains are proteolytic and produce protease activity equal to or greater than that found with other proteolytic ruminal bacteria such as *Ruminobacter amylophilus* or *Prevotella ruminicola*. *B. fibrisolvens* produces peptidases and was identified by Bladen et al., 1961; Scheifinger et al., 1976) as an important ammonia-producing rumen organism, although it is much less active in this regard than some of the obligate amino acid fermenting species isolated more recently (Russell et al., 1988; Attwood et al., 1998; Paster et al., 1993). It has been hypothesized that this proteolytic activity, in addition to providing nitrogen for growth, may be important in making starch contained in granules embedded in protein matrices more available (McAllister et al., 1990; McAllister et al., 1993).

Recently it was discovered that *B. fibrisolvens* strains commonly produce compounds (Kalmokoff et al., 1997; Kalmokoff et al., 1999) that inhibit the growth of a number of different bacterial species including other ruminal bacteria—even other strains of *B. fibrisolvens* themselves. The bacteriocins, Butyrivibriocin AR10 and OR79A, were isolated and characterized. The effect of bacteriocin activity on *B. fibrisolvens*' ecology is unknown but could be to enhance the ability of this organism to compete with other species in the highly competitive rumen environment.

Applications

At present, there are no biotechnological applications of *Butyrivibrio* sp. Because *B. fibrisolvens* produces a large array of extracellular polysaccharide-degrading enzymes, these organisms may represent a rich source of these enzymes and of genes for cloning. A recombinant yeast strain was constructed that contained an endo-glucanase from *B. fibrisolvens* to attempt to exploit this polysaccharide-degrading capacity (van Rensburg et al., 1997; van Rensburg et al., 1994). Applications to biomass fermentors also may be possible because *B. fibrisolvens* is a major portion of the xylanolytic isolates obtained from napier grass-fed anaerobic digesters (Sewell et al., 1988). *B. fibrisolvens* strains also produce extracellular polysaccharides (EPS) containing unusual sugars (Stack, 1988a; Stack and Weisleder, 1990; Stack et al., 1988b; Stack and Weisleder, 1990). The structures of some of these EPS have been elucidated and the potential for industrial use of one of these has been investigated (Ha et al., 1991; Ferreira et al., 1995; Ferreira et al., 1997).

Most interest in the commercial exploitation of *B. fibrisolvens* lies in its function in the rumen. Because it is a numerically important species under a variety of feeding conditions, *B. fibrisolvens* has been identified as a potential target for genetic manipulation. The goal of such an approach is to develop inocula that can be used to improve the digestion of feeds in agriculturally important ruminant livestock species, such as cattle and sheep. Towards this end a recombinant strain of *B. fibrisolvens* was developed that expresses dehalogenase activity and thereby the ability to detoxify the plant toxin fluoroacetate (Gregg, 1995; Gregg et al., 1994). The recombinant strain was successfully introduced into the rumen of sheep conferring resistance to those animals consuming this toxic agent. This strain was not developed further because of concerns over environmental release of this recombinant organism.

Lachnospira

Introduction

Lachnospira sp. are Gram-positive, nonsporeforming, obligately anaerobic, motile, rod-shaped, pectin-fermenting bacteria isolated from the intestinal tracts of animals. The genus is composed of two species, *L. multipara* and *L. pectinoschiza*. Originally isolated as curved or helical rods that formed filamentous or "wooly" colonies, this genus was given the name *Lachnospira*, or wooly hair coil, to emphasize this unique characteristic (Bryant and Small, 1956b). These orig-

inal isolates from the rumen also formed many fermentation products, thus the name *L. multiparus* (now *L. multipara*). More recently a second species, *L. pectinoschiza*, was isolated from cecal contents and feces of pigs (Cornick et al., 1994). Although this species does not form the characteristic "wooly" colonies, analysis of the 16S rRNA sequence indicated a close relationship with *L. multipara* and therefore this organism was placed in the same genus. The name *L. pectinoschiza* given to this species identifies its "pectin splitting" activity.

Phylogeny

The *Lachnospira* are placed phylogenetically within cluster XIVa of the *Clostridium* subphylum, as defined by Collins et al., 1994. Cluster XIVa contains a diverse array of Gram-positive bacteria including members of the genera *Clostridium*, *Coprococcus*, *Eubacterium*, *Ruminococcus*, *Syntrophococcus*, *Roseburia*, "*Acetitomaculum*" and *Butyrivibrio*. The *Lachnospira* form a monophyletic group within this cluster with *L. multipara* and *L. pectinoschiza* grouping together.

The phylogenetic relationship of the two species of *Lachnospira*, as determined by 16S rRNA analysis (Cornick et al., 1994), agrees with the results of DNA-DNA hybridization and extracellular polysaccharide analysis (Mannarelli et al., 1990b). *L. multipara* has a similarity to *L. pectinoschiza* of approximately 94% and to *C. celecrescens*, *E. rectale* and *R. cecicola* of 90 to 91%. *L. pectinoschiza* is more closely related to *R. cecicola*, with a similarity of 93%. (See Fig. 1.)

Habitat

Lachnospiras are normal inhabitants of the rumen and also have been isolated from the gastrointestinal tracts of pigs, reindeer, and iguanas (Stewart and Bryant, 1988; Cornick et al., 1994; McBee and McBee, 1982; Mathieson et al., 1987). Although generally present in low numbers (e.g., 0.1% of total bacteria) in rumen contents of animals fed many diets, *Lachnospira multipara* can be present in high numbers when ruminants are fed diets rich in pectin (Bryant et al., 1960). *Lachnospira pectinoschiza* was isolated as a "pectinophile" from the cecum of the pig and also could be recovered from feces of these animals. It is likely that *Lachnospira* sp. will be found in the gastrointestinal tracts of other animals, when adequate selective isolation procedures or specific detection methods are developed for these organisms.

Isolation

LACHNOSPIRA MULTIPARA All *Lachnospira multipara* strains are pectinolytic and have been isolated from ruminal contents with media containing pectin as the only added energy source (Dehority, 1969). These media are only partially selective as colonies of other pectin-fermenting bacteria such as *Butyrivibrio fibrisolvens* and *Prevotella ruminicola* are also obtained. More selective isolation media or enrichment procedures for *L. multipara* are not known. The type strain is resistant to kanamycin and neomycin, so it might be possible to devise a selective medium containing pectin and these antibiotics (Wang et al., 1969). A similar approach using starch and kanamycin was successfully applied to the selective isolation *Streptococcus bovis* from the rumen (D. Odelson, personal communication). *L. multipara* has few nutritional requirements (Bryant and Robinson, 1962), which might also be incorporated into the development of more selective isolation procedure.

Lachnospira pectinoschiza Cornick et al. (1994) isolated L. pectinoschiza from pig cecal contents and feces using procedures developed to isolate "pectinophilic" bacteria from other environments. Pectinophiles are described as organisms able ferment only pectin and a few related compounds. Their approach was to isolate pectin-fermenting bacteria from a synthetic, salts-yeast-extract polygalacturonic acid medium and then to screen the isolates for the ability to use other carbohydrate sources. Although they were able to isolate L. pectinoschiza strains, these represented only a small percentage of the total obtained using this procedure.

IDENTIFICATION

Lachnospira multipara Lachnospira multipara is perhaps the only species of ruminal bacteria that can be presumptively identified on the basis of colonies formed in agar media (Bryant, 1963). Other species will on occasion form similar filamentous colonies, so identity must be confirmed by additional characterization. With nutrient-rich rumen fluid-carbohydrate media, surface colonies of *L. multipara* are large (3 to 5 mm in diameter), flat, white and filamentous (Bryant, 1974; Bryant, 1986b). Colonies within agar media are quite distinctive, appearing as white woolly balls. The typical appearance of *Lachnospira* is a curved rod (0.4 to 0.6 mm x 2 to 4 mm long) with bluntly rounded ends. In wet mount preparations, the organisms appear singly or in pairs of motile, curved rods. Most cells show some translational motility that is characterized by frequent tumbling and movement in circular

patterns. Although originally described as having polar, monotrichous flagellation (Bryant and Small, 1956b), it was later shown that the flagellum is subterminally or laterally attached. Cells generally stain weakly Gram-positive, but can be Gram-negative in older cultures. However, the ultrastructure of the cell wall appears to be that of a Gram-positive bacterium (Cheng et al., 1979; Hespell et al., 1993). Isolated peptidoglycans (PG) contained glucosamine, muramic acid, alanine, and meso-diaminopimelic acid. The PG preparations did not contain galactosamine, which was found in PG isolated from *Butyrivibrio fibrisolvens*.

Many *L. multipara* strains are capable of very rapid and extensive growth in carbohydrate-peptone-yeast extract media. Under these conditions, the cells often form very long chains or filaments (Bryant, 1986a). The cells in these structures are only slightly curved and have rounded ends. Quite often these structures become entwined with one another causing growth in liquid media to flocculate and readily settle out. This floc may be quite difficult to disperse and may adhere to glass surfaces. Growth of some strains can result in viscous cultures, suggesting the production of a polysaccharide material. An extracellular polysaccharide composed of rhamnose, mannose, galactose, and glucose has been isolated from cultures of the type strain (Mannarelli et al., 1990b).

Whereas all strains do not grow on cellulose or xylans and some strains may show weak growth on starch, all *L. multipara* strains rapidly ferment pectin and polygalacturonate (Bryant and Small, 1956b; Bryant, 1986; Bryant, 1963). The range of soluble carbohydrates used is limited and includes glucose, fructose, sucrose, cellobiose, esculin, salicin, and usually glucuronate. Xylose is weakly or variably fermented. The main fermentation products made from glucose are lactate, formate, acetate, ethanol, carbon dioxide, and some hydrogen gas. Small amounts of acetoin or propionate may be formed, but no butyrate or succinate is made. Biochemical tests for nitrate reduction, catalase, indole or hydrogen sulfide are negative. The GC of DNA from the type strain, D32^T is 38 mol% (buoyant density; Mannarelli et al., 1990b; T$_m$; Cotta, unpublished observation).

Lachnospira pectinoschiza The information available on characteristics of *Lachnospira pectinoschiza* is based on the description by Cornick et al., 1994. Surface colonies of *L. pectinoschiza* on agar media are opaque, circular with wavy edges, umbonate, and 3 to 5 mm in diameter. Growth only occurs under strictly anaerobic conditions. *L. pectinoschiza* cells are rod-shaped (0.36–0.56 mm wide × 2.4–3.1 mm long).

Although spore-like inclusions were sometimes observed in cells, survivors were not detected following heating or ethanol treatment. Cells are actively motile by means of peritrichous flagella (6–18 per cell). The cells stain Gram-positive and this cell ultrastructure was confirmed in electron micrographs of thin sections. The GC content of *L. pectinoschiza* strains ranged from 42–45 mol%. *L. pectinoschiza* grows rapidly on pectin and polygalacturonic acid, but few other carbohydrates are fermented. Lactose, gluconic acid, and cellobiose will also support growth. Fructose is used only after a long lag period. Growth occurs between 30–45°C, but not at 25°C or 50°C. The major products of pectin fermentation are acetic and formic acids, with smaller amounts of ethanol and carbon dioxide. Methanol is also produced during fermentation of pectin, presumably due to the action of pectin methylesterase. Ethanol is a major product when *L. pectinoschiza* is grown on lactose, cellobiose, and fructose. Lactate and hydrogen were detected. Tests for nitrate reduction, catalase, esculin and gelatin hydrolysis are negative.

CULTIVATION Members of *Lachnospira* are all strictly anaerobic bacteria, and appropriate steps should be employed to remove and exclude oxygen from growth medium (e.g., use of the technique of Hungate and modified by Bryant, 1972). The complex medium RGM (Table 2) can be used to grow strains of these bacteria as well as many other species of gastrointestinal anaerobes (Hespell et al., 1987). Peptides in the form of trypticase or other peptones are not required by *L. multipara*, but often stimulate growth when added to ammonia-containing defined media (Bryant and Robinson, 1962). Acetate was stimulatory to growth in defined media without peptone. *L. pectinoschiza* grows well in similar media with yeast extract (Cornick et al., 1994). The precise vitamin and other growth requirements for most strains of *Lachnospira* have not been determined. Strains are is generally grown at 37–39°C, but growth occurs between 30–45°C.

PRESERVATION Most strains of *Lachnospira* can be maintained for long times by storage of cultures in liquid nitrogen or in ultracold freezers (Hespell and Canale-Parola, 1970). Short-term storage (6–15 months) is possible by placing glycerol-containing cultures in normal (–20°C) freezers (Teather, 1982a). These organisms also can be preserved indefinitely by lyophilization.

PHYSIOLOGY Biochemical and physiological studies with *Lachnospira* sp. have mostly dealt with pectin degradation. *L. multipara* is capable of extensive maceration of clover and grass leaves, which can contain 2–8% pectin (Cheng et

al., 1979). *L. multipara* produces pectin lyase and pectin methylesterase activities, but appears to lack a polygalacturonase activity (Silley, 1985). An extracellular polygalacturonate lyase has been partially purified from strain 685 (Wojciechowicz et al., 1980). The enzyme required calcium for activity and was most active toward polygalacturonate, producing mainly the unsaturated digalacturonate from random attack on this substrate. Evidence for exopolygalacturonase activity in culture fluids of this strain (685) also was noted. In contrast, work with other strains (i.e., D15d and 2389) found no evidence for this last type of activity (Silley, 1985). However, both pectin lyase and pectin esterase activities were detected in these two strains. More recently, a detailed study of the kinetics of product formation by pectin lyase isolated from strain D15d indicated polygalacturonic acid was degraded by a random endolytic attack, producing primarily unsaturated trimers as the limit product (Preston et al., 1991). Production of dimer and trimer terminal products is consistent with the inability of *L. multipara* to ferment monomeric products of pectin degradation.

L. petinoschiza also produces pectin lyase and pectin methylesterase activities, and like *L. multipara* appears to lack an extracellular polygalacturonase activity (Cornick et al., 1994). Pectin lyase activity was more active against polygalacturonic acid, was calcium dependent, and was most active under alkaline conditions. Because unsaturated dimer was the only products detected, this enzyme may attack polygalacturonic acid in an exo-fashion.

ECOLOGY *Lachnospira multipara* is considered an ecologically important species of ruminal bacteria and can be a major constituent of the bacterial population under certain dietary conditions. *L. multipara* strains are the primary pectin fermenters isolated from ruminal contents of animals fed diets high in pectin (e.g., lush legumes, and citrus pulps). With animals fed rich ladino clover, 16–31% of the total bacterial isolates were *Lachnospira* strains (Bryant et al., 1960). Strains also have been isolated from ruminal contents of animals fed alfalfa hay when media containing pectin as the sole carbohydrate source are used (Dehority, 1969). In contrast to other pectin fermenting bacteria of the rumen (e.g., *Butyrivibrio fibrisolvens*), *L. multipara* strains have a limited range of carbohydrates that they ferment. Besides pectin, most strains ferment sucrose, fructose, and glucose, which are usually present at substantial levels in fresh, young forages. *L. multipara* is capable of invading and causing maceration of these types of plant materials (Cheng et al., 1979). During pectin fermentation, methanol is formed as a

product of pectin methyl esterase activity. In the rumen, this compound can be cross-fed to methanol-utilizing bacteria such as *Eubacterium limosum*. Evidence for this type of cross feeding has been demonstrated with cocultures of these species (Rode et al., 1981). Although *L. multipara* is very active in the degradation of pectin (a plant polysaccharide), synergisms in the growth and utilization of plant polysaccharides when cocultivated with other species of plant polysaccharide-utilizing species could not be demonstrated (Osborne and Dehority, 1989). The ecological significance of *L. pectinoschiza* in the swine gastrointestinal tract is unknown at this time.

Roseburia

INTRODUCTION The genus *Roseburia* contains a single species, *R. cecicola*, a Gram-negative, non-sporeforming, obligately anaerobic (slightly curved) rod-shaped bacterium isolated from the scrapings of cecal mucosa of mice. It is named after Theodor Rosebury, an American microbiologist who described and studied microorganisms indigenous to humans. The species name *cecicola* is used to indicate that this organism is a "cecum dweller" (Stanton and Savage, 1983a).

PHYLOGENY *Roseburia cecicola* is placed phylogenetically within cluster XIVa of the *Clostridium* subphylum, as defined by Collins et al., 1994. Cluster XIVa contains a diverse array of Gram-positive bacteria including members of the *Clostridium*, *Coprococcus*, *Eubacterium*, *Ruminococcus*, *Syntrophococcus*, *Lachnospira*, "*Acetitomaculum*" and *Butyrivibrio*. The phylogenetic relationship of *Roseburia*, as determined by 16S rRNA analysis (Cornick et al., 1994), indicates that *L. pectinoschiza* is the closest sequenced relative, with a similarity of 93%. (See Fig. 1.)

HABITAT *Roseburia cecicola* has been isolated from mucosal scrapings taken from the ceca of conventional laboratory mice (Stanton and Savage, 1983b), but the occurrence of this species in other animals is not known at this time. *R. cecicola* is motile, and motility and chemotaxis have been suggested as important characteristics for microorganisms that colonize mucosa and other tissues of animals. In mucosal scrapings, motile bacteria outnumber nonmotile bacteria by two to one (Stanton and Savage, 1983b). Stanton and Savage, 1984 showed that while motility was not essential for *R. cecicola* to colonize the ceca of gnotobiotic mice, it may be required for colonization of conventional mice. Using antibodies made to the flagellin protein of *R. cecicola*, this organism was shown to associate with the mucosal epithelium (Martin and Savage, 1984).
Fig. 3. Schematic representation of procedures to isolate motile bacteria from the mouse cecal mucosa. (A) Motile bacteria that swam through broth in a capillary tube were selected. (B) Motile bacteria were selected based on their colony morphology in semisolid medium. (by T. Stanton, reproduced with permission.)

Fig. 4. Phase-contrast micrographs of R. cecicola strain GM[T] cells (wet mount preparations). Cells were cultured in VTY broth and were in the exponential phase of growth. Each cell had a fascicle of 20–35 flagella (arrowheads). Bar = 5 μm. (by T. Stanton, reproduced with permission.)

ISOLATION *Roseburia cecicola* strain GM (type strain) was isolated using a procedure that selected for motile microorganisms present in the mucosal scrapings from mice ceca (Stanton and Savage, 1983b; Fig. 3). This approach involved inoculating a capillary tube filled with growth media. After incubation, the end of the tube opposite the inoculation end was broken off, some of the contents were removed and used to inoculate agar media to obtain individual colonies. This selection procedure is based on the concept that motile bacteria would migrate through the tube, whereas nonmotile bacteria would remain near the tube inoculation end. A selective medium containing soluble starch and the antibiotics nalidixic acid and tetracycline was useful in the selective enumeration of *R. cecicola* cells present in the cecum of mice inoculated with a defined population of microorganisms (penta-associated; Stanton and Savage, 1984). This medium, however, was not sufficiently selective to exclude all other cecal bacteria present in conventional mice.

IDENTIFICATION The information available on characteristics of *R. cecicola* is based on the description by Stanton and Savage, 1983a. Surface colonies of *R. cecicola* on agar media (0.7% Noble agar) are circular with a smooth edge, white, and 1.5 to 3.0 mm in diameter. The colonies have a granular appearance and are mucoid in texture. Subsurface colonies appear lenticular in shape, brownish white, and are about 1.0 mm in diameter. Growth only occurs under strictly anaerobic conditions. *R. cecicola* cells are curved rods (0.5 mm wide × 2.5 to 5.0 mm long) with rounded ends. Spores are not formed. Cells are actively motile and in wet mount preparations a single, large fascicle of flagella can be seen to arise from the concave cell side (Fig. 4). The fascicle is subterminally located and consists of 20 to 35 flagella. The cells stain Gram-negative and electron microscopic observations of thin sections indicate this bacterium has a multi-layered cell wall structure The presence of 2-keto-3-deoxyoctanoate (KDO) in cells is also indicative of a Gram-negative cell envelope (Martin and Savage, 1985). *R. cecicola* cells are catalase negative and the GC content of strain GM[T] (ATCC 33874) DNA is 42.3 mol%. *R. cecicola* does not ferment cellulose, xylan, or pectin, but does grow with starch as the energy source. Dextrin, amylopectin, and glycogen also support growth. Cellobiose, maltose, sucrose, raffinose, glucose, galactose, glucuronate, xylose, glycerol and sorbitol are fermented. During fermentation

of glucose, equimolar amounts of acetate are utilized and large amounts of butyrate and carbon dioxide are formed. Small amounts of ethanol also are made and hydrogen gas has been detected as a product. These characteristics clearly distinguish *R. cecicola* from other genera of Gram-negative, obligately anaerobic, non-sporeforming, rod-shaped bacteria (e.g., *Bacteroides*, *Butyrivibrio*, *Lachnospira*, *Selenomonas*, *Succinivibrio*).

CULTIVATION *Roseburia cecicola* is a strictly anaerobic bacterium and appropriate steps should be employed to remove and exclude oxygen from growth medium (e.g., use of the technique of Hungate and modified by Bryant, 1972). The complex medium RGM (Table 2) can be used to grow *R. cecicola* strains as well as many other species of gastrointestinal anaerobes (Hespell et al., 1987). The precise vitamin and other growth requirements for *Roseburia* strains have not been determined. *R. cecicola* grows optimally at 37°C and will also grow at 30°C, but not at 22°C or 45°C.

PRESERVATION *Roseburia cecicola* strains can be maintained for long times by storage of cultures in liquid nitrogen or in ultracold freezers (Hespell and Canale-Parola, 1970). Preservation by lyophilization under anaerobic conditions may be possible, and strains obtained from culture collections are provided in this form. Short-term storage (6–15 months) is possible by placing glycerol-containing cultures in normal (–20°C) freezers (Teather, 1982a).

PHYSIOLOGY Studies done with *R. cecicola* have centered on investigations of the role of motility in its colonization of the mouse gastrointestinal tract. Through the use of UV-induced motility mutants, Stanton and Savage, 1984 demonstrated that motility was not essential for the colonization of the cecum of germ-free mice. Motility, however, was required for successful colonization by *R. cecicola* when other species of gastrointestinal microorganisms were present. The flagella have been isolated from this organism using mechanical shearing (Martin and Savage, 1985) and are composed of a single protein (flagellin) with an estimated molecular weight of 42 kDa. The gene coding for this flagellin protein has been cloned and sequenced (Martin and Savage, 1988a). Based on the sequence data, the flagellin protein's molecular weight was estimated to be 31,370 Da, and comparisons with sequences of other bacterial flagellins revealed a greater similarity to those of Gram-positive rather than those from other Gram-negative organisms. During these studies, it was also dis-

covered that high molecular weight DNA could not be prepared from this organism if *R. cecicola* is exposed to oxygen prior to cell lysis (Martin and Savage, 1988b). A substance responsible for this activity was isolated from cell lysates. The low molecular weight (2.8 kDa) substance catalyzed the degradation of DNA by a mechanism consistent with the involvement of hydroxy radicals, which can be produced from other oxygen reduction products (αO_2^- and H_2O_2; O'Conner and Savage, 1993).

CHAPTER 1.3.6

The Genus *Veillonella*

PAUL KOLENBRANDER

Introduction

Bacteria of the genus *Veillonella* Prévot are anaerobic, Gram-negative cocci (Rogosa, 1984). The type species was originally described by Veillon and Zuber (Veillon and Zuber, 1898) as *Staphylococcus parvulus* and renamed by Prévot (Prévot, 1933) as *Veillonella parvula*. Although all strains of *Veillonella* are phenotypically very similar, seven species are recognized by DNA homology analysis (Mays et al., 1982). The seven species can be identified by restriction fragment length polymorphism (RFLP) analysis of restriction enzyme digests of their 16S ribosomal DNA (Sato et al., 1997a). Veillonellae are found in the alimentary canal of warm-blooded animals and can constitute a major fraction of the bacteria on the epithelial surfaces of the human oral cavity.

Veillonellae are characterized by their unusual metabolism. They generally are unable to ferment carbohydrates including glucose but grow well anaerobically on lactate, pyruvate, malate or fumarate. They possess methyl malonyl-CoA decarboxylase, which belongs to a unique class of vectorial catalysts that convert the free energy of decarboxylation reactions into an electrochemical gradient of sodium ions (Dimroth, 1985). The enzyme catalyzes an essential reaction in the fermentation of lactate and provides an energy conservation mechanism, which contributes to their high cell yields per mole of lactate fermented.

Human oral veillonellae live in a lotic (flowing) environment and have developed mechanisms to colonize exposed surfaces. Veillonellae are only weakly adherent to hard and soft tissue surfaces, but they can adhere to other genera of oral bacteria (Gibbons and Nygaard, 1970; Hughes et al., 1988) and thus become part of multispecies bacterial networks (intergeneric coaggregations; Kolenbrander, 1988a). Many of these coaggregation partners are early colonizers that are capable of primary attachment to soft and hard tissue surfaces. Intergeneric coaggregation is highly specific in that veillonellae from one econiche, for example, the tongue dorsum, adhere to other bacteria found in that econiche but usually do not bind to bacteria from other econiches, for example, subgingival plaque (Hughes et al., 1988). Thus, interactions among oral bacteria appear to be important determinants in bacterial colonization of different surfaces.

Because of their unusual metabolic capabilities, including their use of the lactic acid produced by other oral bacteria from carbohydrate fermentation, the veillonellae form an essential link in the natural food chain. Their rise in numbers in the oral ecosystem immediately follows or parallels the proliferation of lactic acid-producing streptococci and actinomyces, both primary colonizers of the tooth surface and mucosal epithelium and both coaggregation partners of veillonellae. These two properties, intergeneric coaggregation and metabolic communication, may contribute significantly to the high numbers of veillonellae found in all dental plaque, whether obtained from healthy sites or diseased sites, which otherwise have very different bacterial populations (Dzink et al., 1988; L. V. H. Moore et al., 1987a; W. E. C. Moore et al., 1985).

Phylogeny

Although they are Gram negative by staining, the veillonellae are phylogenetically more closely related to Gram-positive species (Tanner et al., 1994; Willems and Collins, 1995). They belong in the *Sporomusa* subbranch of the *Clostridium* subphylum of the Gram-positive phylum of bacteria. The *Sporomusa* subbranch also includes closely related genera *Acidaminococcus* and *Megasphaera* as well as *Selenomonas*, which is related at a deeper level. Grouping the motile-rod selenomonads with the sessile-coccus veillonellae is consistent with the unusual shared presence of cadaverine and putrescine in their cell walls (Stackebrandt et al., 1985).

Taxonomy

The following are among the few positive phenotypic traits that are recognized for strains of veillonellae: small (0.3 to 0.5 μm), Gram-

negative cocci; usually occur in pairs; anaerobic growth on lactate or pyruvate, with accompanying production of propionic and acetic acids, CO_2, and H_2; and nitrate reduction (Rogosa, 1964a). Known variations of these properties include cells arranged in masses, short chains or single cells, and resistance to Gram-stain decolorization. Aerobic respiration of lactate or oxaloacetate occurs (Rogosa, 1964a) and some strains of V. *parvula* can grow aerobically in static culture on lactate (C. Hughes and P. Kolenbrander, unpublished observations) indicating that not all veillonellae are strict anaerobes. Some strains require putrescine or cadaverine (Rogosa and Bishop, 1964b) and some produce H_2S (Rogosa and Bishop, 1964c). Carbohydrates are not fermented (except for fructose by most strains of *V. criceti*, which are found in the oral cavity of hamsters; Mays et al., 1982).

Serological groupings were used to distinguish strains of animal and human origin (Rogosa, 1965a). Many of these strains were included in the 116 veillonellae examined for DNA homology (Mays et al., 1982). Seven DNA homology groups distinct at the species level were found (Table 1), and these correspond to the seven species recognized in {Bergey's Manual of Systematic Bacteriology} (Rogosa, 1984). Ribosomal RNA homology (16S and 23S) studies revealed three clusters with average intracluster homology values of greater than 90% and only 60 to 70% intercluster homology values (Johnson and Harich, 1983). *Veillonella atypica*, *V. caviae*, *V. dispar*, *V. rodentium*, and *V. parvula* belong to one cluster. *Veillonella criceti* and *V. ratti* are in a second cluster, and the third cluster consists of two strains of the "3312A" homology group, which comprise an unnamed species.

Veillonella are nonmotile and nonsporeforming. They do not use amino acids as a primary energy source and produce only sparse growth in a complex medium without added lactate, pyruvate, or other metabolizable intermediates. Together with *Acidaminococcus* and *Megasphaera*, they comprise the family *Veillonellaceae* (Rogosa, 1984). The GC content of the DNA of *Veillonella* species is 40.3 to 44.4 mol%, for

Acidaminococcus it is 56.6 mol%, and for *Megasphaera* it is 53.1 to 54.1 mol%. Unlike veillonellae, acidaminococci degrade amino acids, forming acetate and butyrate, while megasphaerae ferment both carbohydrates and organic acids but are inactive on amino acids (Rogosa, 1971). The end products of *Megasphaera* fermentation in a complex medium are acetate, butyrate, caproate, valerate, propionate, isobutyrate, and isovalerate. Colonies of *Veillonella* but not *Acidaminococcus* or *Megasphaera* exhibit a pink to red fluorescence on brain heart infusion agar when exposed to longwave (366 nm) UV light (Chow et al., 1975a). All species of *Veillonella* exhibit the fluorescence on brain heart infusion agar containing either sheep or horse blood (Brazier and Riley, 1988). The common human species, *V. atypica*, *V. dispar*, and *V. parvula*, do not fluoresce on blood-agar base containing either type of blood unless the agar contains δ-aminolevulinic acid. The fluorescence fades rapidly (5 to 10 minutes) on exposure to air and the pigment is typical of metal-free porphyrins.

Differentiation among the species of veillonellae on the basis of commonly used phenotypic tests is difficult, if not impossible. Decomposition of hydrogen peroxide, once used to differentiate between *V. parvula* and *V. alcalescens*, has been reported to vary among subcultures of the same strain (Mays et al., 1982). Thus, *V. alcalescens* has been renamed as *V. parvula*. By using defined culture conditions and cell-extraction procedures, distinct polyacrylamide gel electrophoretic patterns of soluble proteins were found for each species (Mays et al., 1982).

Habitat

Normal Human Oral Flora

Veillonellae are the most numerous anaerobes in human saliva (Sutter, 1984), where they are found at concentrations of 1.7 to 6.9 x 10^7/ml (Richardson and Jones, 1958; Rogosa et al., 1958), and constitute from 5% (Liljemark and Gibbons, 1971) to about 16% (Hardie and Bowden, 1974) of the cultivable anaerobic flora. Almost 10% of the total cultivable anaerobic flora from the tongue dorsum consist of veillonellae (Liljemark and Gibbons, 1971). In supragingival plaque, estimates of veillonellae as a percentage of total bacteria have ranged from about 1% (Liljemark and Gibbons, 1971) to 5% (L. V. H. Moore et al., 1987a; W. E. C. Moore et al., 1985). Direct comparison of the subgingival and supragingival plaque bacteria isolated from healthy sites indicates that about 4 and 5%, respectively, are veillonellae (L. V. H. Moore

Table 1. Characteristics of the type strains of the seven recognized species of the genus *Veillonella*.

Species	ATCC no.	Serogroup	Origin
V. atypica	17744	V	Human
V. caviae	33540	none	Guinea pig
V. criceti	17747	I	Hamster
V. dispar	17748	VII	Human
V. parvula	10790	VI	Human
V. ratti	17746	III	Rat
V. rodentium	17743	II	Hamster

et al., 1987b; W. E. C. Moore et al., 1985). While the veillonellae found on the tongue dorsum are either strains of *V. atypica* or *V. dispar* (Hughes et al., 1988), those found in subgingival plaque samples are primarily *V. parvula* (L. V. H. Moore et al., 1987a; W. E. C. Moore et al., 1985). Veillonellae isolated from saliva and buccal mucosa are mostly *V. atypica* and *V. dispar* (Hughes et al., 1988). *V. atypica* is one of three species of oral bacteria that contribute most to changes in subgingival flora composition during puberty and is one of two species that is particularly associated with teenagers (W. E. C. Moore et al., 1993). *V. parvula* is isolated from subgingival plaque with *Actinomyces odontolyticus*, and these two bacterial species are among the most commonly detected anaerobes in subcutaneous abscesses of intravenous drug users (Summanen et al., 1995). Of the seven taxonomically recognized *Veillonella* species (Rogosa, 1984), *V. atypica*, *V. dispar*, and *V. parvula* are indigenous to the respiratory and intestinal tracts of humans, and the other species are distributed among ruminants, rodents, and pigs.

Experimental Animal Models

Veillonellae are among the predominant microbes of the saliva, tongue dorsum, buccal mucosa, and gingival crevice of both the plaque-susceptible and plaque-resistant rats that were derived from the Wistar Kyoto strain (Isogai et al., 1985). On the basis of total anaerobic cultivable flora, veillonellae were the most numerous bacteria from subgingival plaque of both STR/N periodontitis-susceptible mice and Swiss-Webster periodontitis-nonsusceptible mice (Wolff et al., 1985). Their numbers remained constant from three to thirteen months, the time interval during which other microbial changes occurred with the advancing periodontitis in the STR/N mice. Thus, the number and distribution of veillonellae in these experimental animals are very similar to those observed in the human oral cavity.

Isolation

The following selective medium was designed by (Rogosa, 1956) and modified (Rogosa et al., 1958) and has been used to isolate veillonellae from the human oral cavity (Hughes et al., 1988).

Distilled water is added to a final volume of 1 liter and the pH is adjusted to 7.5 before autoclaving. Vancomycin is added at 7.5 μg per ml before pouring plates. The plates are incubated anaerobically under an atmosphere of 80% N_2, 10% CO_2, and 10% H_2 at 37°C for 48 hours. A commercial medium based on this recipe is

Table 2. Selective Medium for *Veillonella* Species

Tryptone	5.0 g
Yeast extract	3.0 g
Sodium thioglycollate	0.75 g
Basic fuchsin	0.002 g
Tween 80	1.0 g
Sodium lactate (60% w/w)	21.0 ml
Agar	15.0 g
$K_2HPO_4 \cdot 3H_2O$	3.0 g
KH_2PO_4	1.0 g
$CaCl_2 \cdot 2H_2O$	0.15 g
NH_4Cl	0.5 g
$MgCl_2 \cdot 6H_2O$	0.05 g
$Fe_2(SO_4)_3$	0.05 g
Yeast extract	0.1 g
Trypticase peptone	0.1 g
Resazurin	0.001 g
$Na_2S \cdot 9H_2O$	0.5 g
Sodium lactate (50%)	10 ml
$NiSO_4 \cdot 6H_2O$	0.5
$MnCl_2 \cdot 4H_2O$	0.5
$FeSO_4 \cdot 7H_2O$	0.5
$ZnSO_4 \cdot 7H_2O$	0.1
H_3BO_3	0.1
$Na_2MoO_4 \cdot 2H_2O$	0.05
$CoCl_2 \cdot 2H_2O$	0.05
$CuSO_4 \cdot 5H_2O$	0.005

available (Bacto *Veillonella* Agar, Difco Laboratories, Detroit, Michigan).

A medium used to enrich for an isolate identified as *Veillonella* spp. from a methanogenic upflow anaerobic sludge blanket reactor is as follows (Slobodkin and Verstraete, 1993):

$KH_2PO_4 \cdot 3H_2O$	3.0 g
KH_2PO_4	1.0 g
$CaCl_2 \cdot 2H_2O$	0.15 g
NH_4Cl	0.5 g
$MgCl_2 \cdot 6H_2O$	0.05 g
$Fe_2(SO_4)_3$	0.05 g
Yeast extract	0.1 g
Trypticase peptone	0.1 g
Resazurin	0.001 g
$Na_2S \cdot 9H_2O$	0.5 g
Sodium lactate (50%)	10 ml

Distilled water is added to a final volume of 1 liter. The medium also contains 1.0 ml of trace elements solution per liter of the following composition (in g/liter of distilled water):

$NiSO_4 \cdot 6H_2O$	0.5
$MnCl_2 \cdot 4H_2O$	0.5
$FeSO_4 \cdot 7H_2O$	0.5
$ZnSO_4 \cdot 7H_2O$	0.1
H_3BO_3	0.1
$Na_2MoO_4 \cdot 2H_2O$	0.05
$CoCl_2 \cdot 2H_2O$	0.05
$CuSO_4 \cdot 5H_2O$	0.005

Ten-ml aliquots of medium were anaerobically dispensed in 17-ml capacity test tubes, gassed with $N_2:CO_2:H_2$ (84:8:8, v/v), and sealed with butyl rubber stoppers and screw caps. Heat sterilization (121°C for 15min) of the

medium caused the formation of an insoluble black precipitate, which appeared to function as a biofilm support for the veillonellae (Slobodkin and Verstraete, 1993).

A defined medium supporting growth of all seven species of *Veillonella* has been tested (Durant et al., 1997). No growth was observed when lactate was omitted. Aspartate, threonine, arginine, and serine when added to the defined medium were metabolized to acetate and propionate.

Nonselective media that have been successfully used to determine the bacterial flora (including veillonellae) of healthy subgingival sites or of periodontally diseased sites are: Brucella agar supplemented with sheep blood and menadione (Williams et al., 1976), MM10 medium (Slots, 1977), trypticase soy blood agar (Newman et al., 1978), and supplemented brain heart infusion blood agar (W. E. C. Moore et al., 1982a).

Identification

Thin sections of veillonellae viewed by electron microscopy exhibit typical Gram-negative surface layers consisting of an outer membrane, peptidoglycan layer, and cytoplasmic membrane (Bladen et al., 1967; Bladen and Mergenhagen, 1964; Tortosa et al., 1981). Phase contrast photomicrographs of the three human species of *Veillonella* are shown in Figure 1. The cells are spherical and are either single or in short chains of two to four cells. Most of the cells are 0.3 to 0.5 μm in diameter.

Identifying fresh isolates to the genus level of *Veillonella* is relatively straightforward. Gram-negative, small spherical cells that reduce nitrate and grow on lactate or pyruvate but not on glucose under anaerobic atmosphere are the primary characteristics. Gas chromatographic analysis of the fermentation end products indicates acetic and propionic acids are the major products, and H_2 and CO_2 are generated as well (Holdeman et al., 1977). Pyrolysis gas chromatography of lipopolysaccharides has been reported to be useful in differentiating *Veillonella*, *Fusobacterium*, and *Bacteroides* (Dahlén and Ericsson, 1983).

Classification to the species level by conventional phenotypic and biochemical tests relies on numerous negative reactions and cannot distinguish the seven species without labor-intensive methods. Methods involving analyses of cellular fatty acids have been developed (L. V. H. Moore et al., 1987b) and found useful in distinguishing the three human species, *V. atypica*, *V. dispar*, and *V. parvula* (Hughes et al., 1988). Sodium dodecyl sulfate-polyacrylamide gel electrophoresis of veillonellae proteins yields distinct profiles for each of the seven species (Mays et al., 1982; Sato et al., 1997b; Tanner et al., 1992).

Rapid-identification systems are being developed, such as RapID ANA II (Innovative Diagnostic Systems, Inc., Atlanta, GA), ANI Card (Vitek Systems, Hazelwood, MO), and AN-Ident and API ZYM (Analytab, Plainview, NY). Another system, the BBL Crystal Anaerobe Identification System, correctly identified the two *V. parvula* strains included in the panel of
Fig. 1. Phase contrast photomicrographs of (A) *Veillonella atypica* PK1910, (B) *Veillonella dispar* PK1913, and (C) *Veillonella parvula* PK1914 isolates from the human oral cavity. Bar = 10 μm. All figures are at the same magnification.

322 clinically significant anaerobes (Cavallaro et al., 1997).

Restriction fragment length polymorphism (RFLP) analysis of PCR-amplified 16S ribosomal DNA (16S rDNA) can rapidly and reliably distinguish the seven species of *Veillonella* (Sato et al., 1997a, b). The 16S rRNA genes are amplified by PCR using the following primers (forward primer sequence: 5′-GTG CTG CAG AGA GTT TGA TCC TGG CTC AG-3′; reverse primer sequence: 5′-CAC GGA TCC TAC GGG TAC CTT GTT ACG ACT T-3′). Digestion of the PCR products of the 16S rDNA using the restriction endonuclease MnlI yields six RFLP patterns for the seven type strains of *Veillonella* (Sato et al., 1997b). The RFLP patterns of *V. atypica* and *V. caviae* are the same, but they can be distinguished by digestion of the 16S rDNA with Sau3AI.

Preservation

Strains survive freezing at −80°C, preferably suspended in blood, and lyophilization.

Physiology

The unusual physiology and special energy-conservation mechanism of veillonellae have been reviewed (Delwiche et al., 1985; Dimroth, 1985; Dimroth, 1994). The veillonellae are unable to use glucose to support growth, and they do not have a functional hexokinase (Rogosa et al., 1965b). Radiolabeled glucose is not incorporated into bacterial cell compounds (Winter and Delwiche, 1975), suggesting that the glucose phosphotransferase system is also absent. Ribose and fructose can be incorporated into nucleic acid (Kafkewitz and Delwiche, 1972) or lipopolysaccharide (Tortorello and Delwiche, 1983; Winter and Delwiche, 1975) but are not fermented. Veillonellae can utilize lactate as carbon and energy source for growth. Pyruvate, fumarate, malate, α-ketoglutarate, and some purines also are substrates for growth. The major end product of fermentative growth is propionic acid along with acetic acid, carbon dioxide and hydrogen. Propionic acid but not acetic acid is toxic to cultured human gingival fibroblasts and may play a role in host tissue damage (Singer and Buckner, 1981).

Fermentation of lactate proceeds through four-carbon dicarboxylic acid intermediates and involves a novel energy conversion mechanism of biotin-dependent sodium-transport methylmalonyl-CoA decarboxylase (Hilpert and Dimroth, 1983). The decarboxylase is membrane bound, is specifically activated by Na$^+$ ions, and

converts part of the energy of the highly exergonic decarboxylation reaction into a sodium ion gradient. This electrochemical gradient of Na$^+$ ions may be used to drive the active transport of the growth substrate. This methylmalonyl-CoA-decarboxylase, which is found in both veillonellae and *Selenomonas ruminantium* (Melville et al., 1988), the oxaloacetate decarboxylase from *Klebsiella pneumoniae* (formerly *K. aerogenes*; Dimroth, 1981), and the glutaconyl-CoA decarboxylase from *Acidaminococcus fermentans* (Buckel and Semmler, 1982) and *Fusobacterium nucleatum* (Beatrix et al., 1990) have been found only in anaerobic bacteria, where they are induced by their respective fermentation pathway substrates (e.g., lactate with the veillonellae). The physiological significance of these enzymes is two-fold. They are essential for growth on appropriate substrates, and they offer a mechanism for energy conservation and thus provide additional energy to that obtained from the fermentation itself.

The five subunits of the *m*ethyl*m*alonyl-CoA *d*ecarboxylase from *V. parvula* are encoded by a clustered set of genes *mmdA* (α), *mmdD* (δ), *mmdE* (ε), *mmdC* (γ), and *mmdB* (β) (Huder and Dimroth, 1993). The α–subunit is 60% identical to the carboxyltransferase domain of rat liver propionyl-CoA carboxylase. The β–subunits of methylmalonyl-CoA decarboxylase and oxaloacetate decarboxylase of *V. parvula* and *K. pneumoniae*, respectively, are 61% identical. Regarding the mechanism of Na$^+$ transport, much of the identical sequence is in the hydrophobic region, and it contains two conserved aspartic acid residues within the putative membrane-spanning helixes (Huder and Dimroth, 1993). Biotin binds to the γ–subunit, which is 29 to 39% identical with biotin domains of other biotin enzymes. The small ε–subunit (5888-Da) is 47% identical to the C-terminal region of the δ–subunit. The five *mmd* genes were cloned and expressed in Escherichia coli to analyze the role of the δ– and ε–subunits (Huder and Dimroth, 1995). The δ–subunit appears to be involved in assembly of the enzyme complex and, thus, necessary for catalytic function; the ε–subunit has no catalytic function but may increase the structural stability of the five-subunit methylmalonyl-CoA decarboxylase complex (Huder and Dimroth, 1995).

V. parvula cannot grow on succinate as sole carbon and energy source, but can decarboxylate succinate during fermentation of lactate or malate (Denger and Schink, 1992; Janssen, 1992). Addition of succinate increases the growth yields by 2.4 to 3.5 g cell dry mass per mole of succinate, which demonstrates that energy is conserved through succinate decarboxylation. This yield reflects a small free energy

change from decarboxylation and is equivalent to only a third of an ATP, indicating that it helps to save energy but is not sufficient to support growth by itself. *V. parvula* uses pyruvate carboxylase and methylmalonyl-CoA decarboxylase, rather than a transcarboxylase as used by *Propionibacterium* spp., for formation and decarboxylation of C$_4$-dicarboxylic acids (Denger and Schink, 1992).

Gluconeogenesis occurs by a reversed glycolytic sequence to glucose-6-phosphate from lactate (Rogosa et al., 1965b), or by an alternate pathway through malate and glyoxylate to 3-phosphoglycerate (Pestka and Delwiche, 1983), rather than going directly from lactate through 2-phosphoglycerate to 3-phosphoglycerate. Lactate carbon is incorporated into six-carbon sugars (Ng and Hamilton, 1974).

The peptidoglycan of some veillonellae contains putrescine or cadaverine, which are required for normal growth. Putrescine and cadaverine are covalently linked to the α-carboxyl group of the D-glutamic acid residue; both are equally incorporated into peptidoglycan, and during normal growth, they occupy over 40% of the residues (Kamio, 1987a; Kamio and Nakamura, 1987b). Other normal constituents of the peptidoglycan are *N*-acetylglucosamine, *N*-acetylmuramic acid, L-alanine, D-glutamic acid, meso-diaminopimelic acid, and D-alanine. The lipopolysaccharide composition includes glucosamine, tridecanoic acid, and 3-hydroxytridecanoic acid in the lipid moiety and contains 2-keto-3-deoxyoctonic acid, glyceromannoheptose and variable components including galactose, rhamnose, glucosamine, and glucose in the polysaccharide moiety (Hewett et al., 1971; Hofstad and Kristoffersen, 1970). The lipopolysaccharide has been shown to be an endotoxin (Mergenhagen et al., 1961). Endotoxin from both *V. parvula* and *V. atypica* suppress microbicidal activity of human neutrophils but do not affect monocyte function (Foca et al., 1990).

The cytoplasmic membrane of *V. parvula* contains an unusual class of polar lipids called plasmalogens (Olsen, 1997), which is found among anaerobes and certain groups of protozoa and most tissues of higher eukaryotes. The plasmalogens are ether lipids and represent chemically the condensation of a fatty aldehyde to glycerol resulting in a vinyl ether. Plasmalogens, plasmenylethanolamine and plasmenylserine, are present in *V. parvula* and are thought to have specific roles in membrane organization and stability (Olsen, 1997).

Purines may be fermented with the production of acetate, propionate, ammonia, urea, CO$_2$, and H$_2$ (Whiteley and Douglas, 1951). Large amounts of gas may be formed. Nitrate is reduced through nitrite and hydroxylamine to ammonia, which is assimilated (Inderlied and Delwiche, 1973; Ruoff and Delwiche, 1977; Yordy and Delwiche, 1979). An unusual type of xanthine dehydrogenase has been purified and characterized from *V. atypica* (Gremer and Meyer, 1996). It is a129-k Da molybdenum-containing iron-sulfur flavoprotein composed of a noncovalent heterotrimer with 82.4-kDa, 28.5-kDa and 18.4-kDa subunits. *V. parvula* and other rumen bacteria produce dipeptidyl peptidases, which cleave dipeptides from the amino terminus of longer peptides. This contributes to the inefficient use of dietary nitrogen by the host animal and causes waste of nitrogenous feed resources and environmental pollution (Wallace et al., 1997).

Genetics

No genetic system has been reported for any of the veillonellae.

Ecology

Ecological Succession Before and After Tooth Eruption

Shortly after birth, veillonellae appear in the human mouth. They are infrequently detectable in newborns one to eight days old but are found in 75% of infants that are 101 days old and in 100% of one-year-old children (McCarthy et al., 1965). The increase in numbers of veillonellae occurs following the colonization of the predominant oral bacterial species, *Streptococcus salivarius*. In a group of 30 edentulous infants ranging in age from 1 to 7 months, *Veillonella* spp. along with *Fusobacterium nucleatum* and *Prevotella melaninogenica* were the predominant anaerobes (Könönen et al., 1992) found in about 70% of the samples of mucosal surfaces and saliva. These children were tested at 32 months (mean age) with primary dentition; *Veillonella* spp. occurred at the same level as in infants, but the other two species were found in every child (Könönen et al., 1994). Bacteria obtained from the tongues of children of ages 8 to 13 months are diverse in composition (Milnes et al., 1993). While *S. salivarius* is the predominant organism and isolated from 94% of the samples, *Veillonella* spp. are isolated from 73% of the samples, and they were consistently present over the 16 month-duration of the study.

Removal of teeth also causes a change in microbial composition, but veillonellae remain the dominant anaerobic organism in the saliva of geriatric edentulous persons (Sato et al., 1993). Veillonellae are not known to adhere well to buccal epithelial cells (Liljemark and Gibbons,

1971), whereas *S. salivarius* adheres very well (Gibbons and van Houte, 1971). Some veillonellae coaggregate with *S. salivarius*, which may provide a mechanism for veillonellae to adhere in the oral cavity (Hughes et al., 1988).

Ecological Succession from Healthy Gingiva to Periodontal Disease

V. parvula is the predominant *Veillonella* in human dental plaque and constitutes between 93 and 98% of the cultivable veillonellae in healthy subgingival sites (W. E. C. Moore et al., 1985), and its numbers increase in gingivitis as compared with healthy subgingival sites (L. V. H. Moore et al., 1987a; Slots et al., 1978). *V. parvula* is a member of the microbial consortium consistently associated with successful osseointegrated dental implants (Lee et al., 1999). Although *V. atypica* and *V. dispar* are usually present in plaque, they normally occur in low numbers and are not associated with any oral diseases.

Two early studies were conducted to examine shifts in the bacterial population of cleaned hard surfaces in the adult human oral cavity. In the first investigation (Slack and Bowden, 1965), an artificial device was positioned to simulate an interproximal site, and in the other study (Ritz, 1967), a professionally cleaned tooth surface was examined. Both studies indicated that veillonellae were detectable along with streptococci after only 24 hours, and that after 3 days, fusobacteria, actinomyces, and a few other bacterial types also were present. Even when the plaque composition on a cleaned tooth surface was monitored at minute or hourly intervals for the first day, veillonellae were rarely found in samples during the first 24 hours (Socransky et al., 1977; Theilade et al., 1982) but constituted about 20% of the strains isolated from 1- and 3-day old dental plaque (Theilade et al., 1982).

Other surveys indicate that veillonellae remain a significant part of the population in both healthy and diseased sites (Dzink et al., 1985; Loesche and Syed, 1978; Syed and Loesche, 1978) and are among the 10 most numerous species of subgingival plaque bacteria under all conditions examined (Dzink et al., 1988; L. V. H. Moore et al., 1987b; W. E. C. Moore et al., 1985), including experimental gingivitis (W. E. C. Moore et al., 1982b), localized juvenile periodontitis (W. E. C. Moore et al., 1985; Williams et al., 1985), adult chronic moderate periodontitis (W. E. C. Moore et al., 1983), and rapidly progressing generalized periodontitis (W. E. C. Moore et al., 1982). In all of these extensive investigations of the microbial composition of dental plaque, veillonellae are always found as numerically significant members of a consortium of bacterial species. Streptococci and actinomyces repopulate cleaned tooth surfaces, and both of these organisms are coaggregation partners of *V. parvula* (Hughes et al., 1988). Further, populations in periodontally diseased sites are dominated by fusobacteria, which are coaggregation partners of all three human *Veillonella* species (Kolenbrander et al., 1989).

Metabolic Communication

Digestion of proteins by protease-secreting bacterial inhabitants of anaerobic consortia would provide amino acids such as L-serine, which is known to enhance lactate metabolism of veillonellae (Hoshino, 1987). Menaquinones, a potential source of vitamin K for other bacteria, are present in some veillonellae (Ramotar et al., 1984). Mixtures of *V. parvula* and *Haemophilus parainfluenzae*, both isolated from the gastric juice of achlorhydric patients, accumulated nitrite during nitrate reduction, and the nitrite concentration could be decreased by including the nitrite-reducing *Neisseria subflava* or *Streptococcus sanguis* (Forsythe and Cole, 1987). Coculturing amylolytic rumen bacteria and lactate-utilizing bacteria (veillonellae) on starch usually produced higher growth yields (Marounek and Bartos, 1987). Growth of *Veillonella* with the lactate-producing *Streptococcus mutans* (Distler and Kroncke, 1980) or lactate- and succinate-producing *Actinomyces* (Distler and Kroncke, 1981) or with *Eubacterium saburreum* (Mashimo et al., 1981) has been demonstrated.

A two-species chemostat consisting of an aerobic bacterium, *Comamonas testosteroni*, and anaerobic *V. parvula* was established with dual limitation of L-lactate and oxygen (Gerritse et al., 1992). Although catalase is detectable in cultures of *V. parvula* and cultures can grow in the presence of oxygen at concentrations below $0.8\,\mu M$ (de Vries et al., 1978), results of this study showed that superoxide anion radicals and catalase were produced. Inhibition of growth of *V. parvula* in air was correlated with a rapid but reversible inactivation of lactate dehydrogenase (de Vries et al., 1978). *C. testosteroni* is an obligate aerobe that can grow on L-lactate as a sole carbon and energy source and can use propionate and acetate, the two major fermentation products of *V. parvula* (Gerritse et al., 1992). Coexistence of the two species occurred only when the chemostat culture was oxygen limited. *C. testosteroni* grew primarily on the end products of lactate fermentation by *V. parvula*, and apparently protected the veillonellae from oxygen inhibition by reducing the oxygen concentration to a tolerable level for the veillonellae (Gerritse et al., 1992). The veillonellae were better competitors for L-lactate even under low oxygen concentrations, which may explain why

the biomass of the veillonellae varied little, but the biomass of *C. testosteroni* increased linearly with increasing oxygen supply. Thus, it appears that the most important determinant for coexistence is the affinity of *C. testosteroni* for oxygen and the sensitivity of *V. parvula* for oxygen.

A consortium of nine oral bacteria in a glucose-limited chemostat was monitored for changes in the composition of the bacterial population accompanying pH changes (McDermid et al., 1986). At pH 7.0 veillonellae and streptococci were most numerous, and, at pH 4.1, veillonellae were numerically second only to *Lactobacillus rhamnosus* (formerly *L. casei*). They regained their same predominance with the streptococci when the pH was returned to 7.0. When the consortium was subjected to a pulse of glucose rather than to a continuous supply, *V. dispar* was the most numerous organism following all the glucose pulses, and it was especially dominant at low pH values of 5.5 to 4.5 (Bradshaw and Marsh, 1998). These experiments show that veillonellae are able to effectively utilize lactic acid produced by a variety of oral bacteria including streptococci and lactobacilli (Delwiche et al., 1985; Mikx and van der Hoeven, 1975) in either acidic or neutral pH environments. In a separate study, persistence and eventual predominance of *V. dispar* along with streptococci in a glucose-limited chemostat inoculated with a tongue scraping are attributed to the ability of veillonellae to utilize the lactic acid end products of other oral bacteria (Basson and van Wyk, 1996).

Similar metabolic communications in vivo are suggested by the observation that incipient carious lesions in the teeth of children have an increased number of *S. mutans* and *Lactobacillus* spp. along with increased numbers of *Veillonella* spp. (Boyar and Bowden, 1985). Also, veillonellae are associated with the dense infections of *S. mutans* on susceptible surfaces related to developing lesions of nursing caries in young children (Milnes and Bowden, 1985). The highest proportions of *Veillonella* spp. were found at sites with the highest numbers of mutans streptococci (Babaahmady et al., 1997). In contrast, veillonellae may protect the tooth surface by removal of the stronger lactic acid and replacement with its own metabolic end products, the weaker acetic and propionic acids. To function in this protective role, veillonellae should increase their numbers quickly in response to small amounts of lactic acid. In accord with this hypothesis, the predominant supragingival flora of caries-free Tanzanian children consisted of unusually high proportions of *Veillonella* spp. (30% to 40% of the total cultivable microflora) along with the oral streptococci (Kilian et al., 1979). Plaque from caries-free adults also contains higher levels of

Veillonella species than does plaque from caries-susceptible adults (Minah et al., 1981).

With gnotobiotic animals, it was shown that *S. sanguis* or *S. mutans* was more cariogenic when either species mono-infected an animal than when associated with veillonellae (Mikx et al., 1972). This caries reduction was interpreted to be due to conversion of streptococcal-produced lactic acid to the weaker acids, acetic and propionic acids, by the veillonellae. A reduction in lactic acid and an increase in acetic acid was shown to occur in dental plaque of gnotobiotic rats hosting an experimental symbiosis of veillonellae and cariogenic streptococci (van der Hoeven et al., 1978). Compared to the high numbers of *S. mutans* found in nursing caries of children, the number of *S. mutans* required to cause caries in gnotobiotic animals is quite low. The reduction in caries by association with veillonellae may occur through the rapid growth response by veillonellae to small amounts of lactic acid, while the dense streptococcal population in nursing caries maintains a high lactic acid concentration and little significant reduction in caries occurs even in the presence of veillonellae.

Epidemiology

Veillonellae are frequently isolated from the inferior conjunctival sacs of normal eyes and anophthalmic cavities (Campos et al., 1994), and they are commonly found in extraoral sites in patients undergoing medical procedures or patients with infections. *V. parvula* is one of the three most frequently isolated anaerobic organisms in ventilator-associated pneumonia (Doré et al., 1996), and it was the only anaerobe isolated in a second study of ventilator-associated pneumonia, where it was considered a nonpathogen (Marik and Careau, 1999). It is isolated as one of several species from ultrasound-guided percutaneous transthoracic aspiration of patients with obstructive pneumonitis (Liaw et al., 1994) and lung abscesses (Mori et al., 1993). It is part of the increased oral anaerobic bacterial load isolated from biofilms associated with human oral carcinomas (Nagy et al., 1998).

Veillonellae are much less frequently isolated from infection sites than the anaerobic streptococci (*Streptococcus*, *Peptococcus*, *Peptostreptococcus*) but are frequently found in neck space infections of children (Ungkanont et al., 1995). They have been isolated as the only bacterial type from patients with endocarditis (Greaves and Kaiser, 1984; Loewe et al., 1946), hepatic abscesses (Lambe et al., 1974), and pleuropulmonary infections (Bartlett and Finegold, 1972). They were present in 14 of 62 specimens of chronic sinusitis (Heineman and Braude, 1963)

and were the only genus isolated in some cases (Frederick and Braude, 1974). They also have been found in bite-wound infections (Goldstein et al., 1984), gynecological infections (Chow et al., 1975a), intra-abdominal abscesses (W. E. C. Moore et al., 1969), pelvic abscesses (Williams, 1977), septicemia and osteomyelitis (Barnhart et al., 1983; Borchardt et al., 1977), pleuropulmonary infections (Bartlett et al., 1974; Martin, 1974), and periodontal disease (W. E. C. Moore, 1987). When isolated from blood cultures, they usually are mixed with other species and probably occur mixed with other species in most isolations from most sources.

They are like the other anaerobes in their susceptibility to the various antimicrobials, and many are resistant to tetracycline at concentrations greater than 10 μg/ml. Thirteen strains of *Veillonella* were among the 601 clinical isolates of anaerobic bacteria tested for minimal inhibitory concentrations of 10 antimicrobial agents (Martin et al., 1972). In periodontal patients undergoing tetracycline therapy, *Veillonella* species along with *Streptococcus* and *Neisseria* that are resistant to tetracycline with minimal inhibitory concentrations as high as 128 μg/ml are frequently isolated (Williams et al., 1979). The DNA from these species, as well as from tetracycline-resistant *Fusobacterium nucleatum* and *Peptostreptococcus anaerobius*, hybridize with a TetM probe, prepared from one of the streptococcal tetracycline-resistance determinants (Roberts and Moncla, 1988). Another tetracycline-resistant determinant normally associated with Gram-positive bacteria, TetL, has been detected in *V. parvula* (Pang et al., 1994). These results suggest that these determinants can exist and confer tetracycline resistance in either aerobic or anaerobic Gram-negative and Gram-positive bacteria.

Veillonellae are readily isolated from the oral cavity of patients, but the numbers isolated vary depending on the patient's oral and medical condition. As compared to the normal flora of the oral cavity, veillonellae in patients with severe xerostomia due to Sjögren's syndrome are greatly reduced in number, whereas the numbers of *Candida* spp. and of *Staphylococcus aureus* increase (MacFarlane, 1984). Veillonellae are isolated as part of the microbial flora from root canal specimens and may be important in endodontic infections (Burnett and Schuster, 1978). *V. dispar* is found in much higher numbers and greater frequency than *V. parvula* in subgingival plaque obtained from patients with non-insulin-dependent diabetes mellitus (Zambon et al., 1988). Despite the variation in numbers of veillonellae with disease condition, these anaerobes appear not to be associated with the risk of oral disease. In a study of dental decay of children's molars shortly after eruption, *S. mutans* and lactobacilli are associated with the development of decay, whereas veillonellae, although consistently present, are not (Loesche et al., 1984). Veillonellae are found in nearly all samples from older adults with a high root surface caries risk, but are not correlated with the disease (Ellen et al., 1985). Thus, the occurrence of veillonellae in human oral infection may be a consequence of ecological changes in the infection site rather than a direct pathogenic property of these bacteria.

Disease

Veillonellae are ubiquitous in the oral cavity, but they produce disease only in rare instances. Two fatal cases of *Veillonella* bacteremia have been reported where *V. parvula* was isolated as a pure culture from the patient's blood (Liu et al., 1998). Veillonellae have been implicated as pathogens in several body sites including bone, heart, liver, lungs, sinuses and the central nervous system. Veillonellae cause bacteremia (Fisher and Denison, 1996) and were found as a monospecies infection in infectious myositis in an immunocompromised patient (Beumont et al., 1995), prosthetic valve endocarditis (Houston et al., 1997; Loughrey and Chew, 1990; Zussa et al., 1994), spinal osteomyelitis (Singh and Yu, 1992), septic sacroiliitis (Pouchot et al., 1992), cervicofacial infection (Jones et al., 1989), or part of multispecies infections in skin and soft tissue of intravenous drug users (Summanen et al., 1995; Wexler et al., 1998). A brief review summarizing the *Veillonella* infections in children cites the recovery of *Veillonella* spp. in 4% of specimens submitted for anaerobic culturing (Brook, 1996). Most of the infections were multispecies but four specimens had pure cultures of veillonellae. *Veillonella* spp. are part of a mixed species population in the upper gut in patients with small intestinal bacterial overgrowth syndrome, where the proximal part of the small bowel harbors abnormally high bacterial numbers (greater than 10^5 bacteria per ml of intestinal juice) for a long time (Bouhnik et al., 1999).

Applications

The inability of *V. parvula* to grow on succinate as sole carbon source and the ability of *V. parvula* to ferment lactate and cometabolize succinate can be exploited; veillonellae convert succinate exclusively to propionate during exponential and stationary growth phases (Samuelov et al., 1990). Succinate decarboxylation to propionate follows a nongrowth-linked pattern, and fermentation of

lactate to propionate follows a growth-linked pattern. Thus, a two-stage continuous culture process involving growth on lactate in the first stage enhances the production of propionate in the second stage by feeding succinate to the effluent broth from the first stage.

Veillonellae have been used to control the growth of *Salmonella typhimurium* and *Salmonella enteritidis* in vitro (Hinton and Hume, 1995). Various ratios of lactate and succinate were used in an agar overlay assay system, and the greatest inhibition was noted when the highest concentration (175 μmol) of both succinate and lactate were used. The inhibition may be due to acidic pH and volatile fatty acids produced by veillonellae. The ability of veillonellae to produce acetate and propionate end products may contribute to the effectiveness of veillonellae-containing probiotic cultures fed to chicks to reduce colonization by salmonellae. *Veillonella* strain CF3, isolated from chicken cecum, multiplied and survived in propionate concentrations of 100 mM or less, and the veillonellae increased in numbers higher than the control environment without propionate, suggesting that veillonella CF3 may possess adaptive mechanisms useful in probiotic cultures fed to chickens (Kwon et al., 1997). The production of acetate and propionate by veillonella strain AU2 from growth on tartrate inhibited the growth of *Listeria monocytogenes*, a Gram-positive food-borne pathogen (Hinton and Hume, 1997).

Reduction of methanogenesis is a way to increase animal weight because methane formed in the rumen represents a loss of energy for the animal. Efforts to improve animal performance have included the addition of fumarate to ruminant feed because many rumen bacteria including *V. parvula* oxidize H_2 by using fumarate as a final electron acceptor and forming primarily propionate as end product (Asanuma et al., 1999). Since H_2 is the main substrate for methane production, these results suggest that the fumarate-utilizing bacteria may compete with the methanogens. The fumarate-utilizing bacteria utilize malate and form similar end products as found with fumarate fermentation. Many of these bacteria including *V. parvula* utilize formate, another substrate for methanogenesis, as an electron donor for fumarate reduction (Asanuma et al., 1999).

Four species isolated from conventional rats were introduced into germ free rats to evaluate the ability of the multispecies consortium to ferment uncooked, amylomaize starch granules that contain a resistant starch fraction composed of a resistant outer shell protecting the granule against chemical or enzymatic degradation (Pacheco-Delahaye et al., 1994). The four-species consortium consisted of a *Peptostrepto-coccus* spp. (non-amylolytic, glucose fermenter), *Eubacterium* spp. (amylolytic), *Enterococcus faecalis* (non-amylolytic, able to hydrolyze maltose), and *V. ratti* (non-amylolytic, able to hydrolyze maltose and maltodextrins). In germ-free rats, only 70% of the amylomaize starch was digested; monospecies associated rats with the non-amylolytic strains *Peptostreptococcus* sp., *Enterococcus faecalis*, or *V. ratti* digested no more amylomaize starch than the germ-free rats, monospecies-associated rats with the amylolytic *Eubacterium* spp. digested up to 92%, but the four-species consortium digested 97%. In the cecum of the four-species associated rats, succinic, propionic and acetic acids increased and D-lactic acid disappeared compared to the cecum contents of germ-free or monospecies-associated rats (Pacheco-Delahaye et al., 1994). These results suggest that *V. ratti* hydrolyzed and fermented maltose and maltodextrins and utilized lactic acid end products of the other members of the consortium.

Adherence

Nichrome Steel Wire Model

The first observation that veillonellae could participate in a special adherence arrangement with other oral bacteria involved the relationship between *V. parvula* V5 (formerly *V. alcalescens*) and *Actinomyces viscosus* T6 (formerly *Odontomyces viscosus*) on nichrome steel wires that were suspended in broth cultures (Bladen et al., 1970). The veillonellae were unable to adhere to the solid supports, whereas the actinomyces growing in sucrose-containing medium formed monospecies biofilms on the wires. Transfer of the biofilm-containing wires to lactate-based medium inoculated with *V. parvula* resulted in a large increase in the amount of biofilm deposited because the veillonellae grew in the lactate medium and were apparently able to attach to the initial colonizers.

The requirement for sucrose during monospecies biofilm formation suggests that glucosyltransferase, an extracellular enzyme that catalyzes the incorporation of the glucose moiety from sucrose into a water-insoluble polysaccharide polymer (Robrish et al., 1972), may be involved in biofilm formation and that direct cell-to-cell contact may not be necessary. The enzyme is elaborated by many oral streptococci including *S. salivarius*, whose extracellular glucosyltransferase can bind directly to *V. parvula* cells (Wittenberger et al., 1977). Such enzyme-bound veillonellae can adhere in large numbers to the smooth wire surface in the presence of sucrose and in the absence of other organisms

(McCabe and Donkersloot, 1977). Thus, adherence of a cell type (veillonella) with no innate ability to adhere to a smooth surface can be effected by a secreted enzyme that is produced by a different cell type (streptococcus) and that catalyzes the formation of an insoluble, adherence-mediating polysaccharide.

Intergeneric Coaggregation

PARTNERS Direct adherence between veillonellae and oral bacteria of other genera was first demonstrated by Gibbons and Nygaard, 1970 who noted coaggregation between *V. parvula* V5 (formerly *V. alcalescens*) and *A. viscosus* T6, coccobacillus 26, and *Neisseria* 17. *V. parvula* V1 (formerly *V. alcalescens*) and *V. parvula* V4 were coaggregation partners of many of the 46 human oral *Streptococcus salivarius* isolates examined for other adherence properties (Weerkamp and McBride, 1980). Coaggregation between *V. parvula* V1 and fibrillar strains of *S. salivarius* was much stronger than with fimbriate strains of *S. salivarius* after one hour of incubation, but after 24 hours both interactions were equally strong (Handley et al., 1987). A bald mutant, *S. salivarius* HB-B, devoid of surface structures was unable to coaggregate with *V. parvula* V1 (Harty and Handley, 1988). Coculturing of *V. parvula* and *Eubacterium saburreum* resulted in cocci-filament associations that remained adherent after vigorous vortex mixing (Mashimo et al., 1981).

In a survey of nearly 200 isolates of veillonella spp., all coaggregated with *Fusobacterium nucleatum*; some coaggregated with *Actinomyces israelii*, *Actinomyces naeslundii*, *Actinomyces odontolyticus*, *Gemella morbillorum*, *Streptococcus salivarius*, *Streptococcus sanguis*, *Rothia dentocariosa*, and *Propionibacterium acnes* (Hughes et al., 1988). The patterns of coaggregation between the veillonellae and their partners delineated four coaggregation groups. None of the veillonellae coaggregated with other veillonellae, which illustrates the predilection for intergeneric coaggregation rather than intrageneric interactions.

MECHANISMS Many of the intergeneric coaggregations are inhibited by lactose (60 mM) and all of the coaggregations with streptococci and actinomyces are prevented by heat (85°C for 30 min) or protease treatment of the veillonella (Hughes et al., 1988). The same treatment of the partner has no effect on the ability of that partner to coaggregate. On the basis of the properties of numerous other coaggregations among oral bacteria (Kolenbrander, 1988a), it is likely that many coaggregations involving veillonellae are mediated by lectin-carbohydrate interactions.

For example, a lactose-sensitive lectin (protease-sensitive surface component) is expressed on the veillonella surface, and its cognate carbohydrate receptor is present on the partner surface.

V. atypica PK1910 coaggregates with oral streptococci by two mechanisms. It coaggregates with some streptococci by a lactose-inhibitable mechanism and with other streptococci by a lactose-noninhibitable mechanism. Coaggregation-defective mutants that specifically lack either or both of these mechanisms with oral streptococci have been isolated (Hughes et al., 1990). Three classes of mutants were isolated. The first class fails to participate in lactose-inhibitable coaggregations with streptococci. The second class fails to coaggregate by the lactose-noninhibitable interactions. The third class, isolated from the first class, fails to coaggregate with any oral streptococci. Two distinct surface molecules mediating either lactose-inhibitable or lactose-noninhibitable coaggregations are sufficient to account for all three types of interactions. The lactose-inhibitable interaction appears to be mediated by a 45-kDa surface protein (Hughes et al., 1992). The protein is present in surface protein preparations of the parent and class 2 mutants but is absent in class 1 and class 3 mutant surface protein preparations. It binds to agarose-lactose beads and is eluted by 100 mM lactose. The putative adhesin does not seem to be the structural subunit of veillonella fimbriae, since no differences in fimbriae were observed by electron microscopy of the parent and all three classes of mutants (Hughes et al., 1992). It is likely that the 45-kDa surface protein is an adhesin that binds at or near the tip of the fimbrial structure as has been observed for a lactose-sensitive adhesin in another human oral Gram-negative bacterium, *Prevotella loescheii* (formerly *Bacteroides loescheii*; London and Allen, 1990; Weiss et al., 1988).

RELATIONSHIP TO COLONIZATION SITE Fifty eight of 59 veillonella isolates obtained from the human tongue dorsum coaggregated with *S. salivarius*, a predominant inhabitant of the tongue (Hughes et al., 1988). However, none of the 58 tongue isolates, which were all *V. atypica* or *V. dispar*, coaggregated with *Actinomyces naeslundii*, *Actinomyces israelii*, and *Streptococcus sanguis* isolated from subgingival plaque. In contrast, 24 subgingival veillonellae, of which 20 were *V. parvula*, coaggregated with the actinomyces, streptococci and other normal inhabitants of subgingival plaque, but they exhibited no coaggregation with strains of *S. salivarius*. Five other subgingival veillonellae failed to coaggregate with subgingival bacteria but did coaggregate with *S. salivarius*. Greater than 80% (87 of 105 strains) of the veillonellae isolated from

buccal mucosa and saliva coaggregated with *S. salivarius*, the predominant streptococcus found in such samples. These results indicate the potential for highly specific, spatiotemporally distinct interbacterial adherence. On the basis of the timing of appearance of various bacteria after tooth eruption and increased age of the host, spatiotemporal adherence is likely to mediate bacterial colonization of different habitats within the oral cavity.

An early observation of interbacterial interactions was the presence of "corn cob" and "test tube brush" morphologies of bacteria in dental plaque (Jones, 1972; Listgarten, 1976). A central rod or filamentous cell was surrounded by clusters of spherical cells in the former and by shorter rods in the latter. These cellular arrangements were commonly observed at the edges of developing plaque rather than in the center or near the tooth surface. Veillonellae easily form corncob structures with fusobacteria when the numbers of veillonellae are in large excess (Fig. 2A). When the numbers of the two cell types are equal, large coaggregates are formed not only with fusobacteria (Fig. 2B), but also with streptococci (Fig. 2C), and actinomyces (Fig. 2D). In each pairing the large coaggregates are composed of an interacting network of both cell types. Smaller coaggregates are visible (large arrows, Fig. 2C and 2D) and even when the partners have the same shape (Fig. 2C), the interaction between the two cell types is clearly seen.
Fig. 2. Intergeneric coaggregation between *Veillonella atypica* PK1910 and other oral bacteria. When the ratio of *Veillonella atypica* PK1910 to *Fusobacterium nucleatum* PK1594 is 10 to 1, (A) coaggregates appear as "corn cobs" where the coccal-shaped veillonellae line up along the length of the slender rod-shaped fusobacteria. Coaggregates appear as clumps of mixed cell-types when equal numbers of: (B) fusobacteria, (C) *Streptococcus oralis* (formerly *S. sanguis*) 34, or (D) *Actinomyces naeslundii* (formerly *A. viscosus*) T14V are combined with the veillonellae. The large arrows in Figs. 2C and 2D indicate small coaggregates composed of a few cells of each cell type; the small arrows in Fig. 2C indicate the large phase-dark streptococcal spheres and the smaller and lighter gray veillonellae; and the small arrows in Fig. 2D indicate the characteristic V-shaped or irregularly shaped actinomyces. Bar = 10 μm. All figures are at the same magnification.

The oral cavity is a lotic environment, which selects for adherent inhabitants. Saliva lubricates and cleanses the mouth and it contains lysozyme and bicarbonate ions that can lyse veillonellae (Tortosa et al., 1981). Adherence to other already attached bacteria on the tooth or mucosal surfaces may protect veillonellae from these lytic activities as well as be their primary means of accretion. For example, a cell surrounded by coaggregation partner cells of a different genus is sequestered and is unable to coaggregate with other bacteria (Kolenbrander and Andersen, 1988b). Likewise, the central cell of a rosette may be protected from harmful molecules by having the outer cells of the rosette inactivate them.

Gnotobiotic Animal Model

Coaggregation in vivo between *V. parvula* V-1 (formerly *V. alcalescens*) and *S. mutans* was demonstrated with a gnotobiotic rat model system (McBride and van der Hoeven, 1981). The *Veillonella* strain could not colonize the teeth but the two strains of *S. mutans* attached and colonized the smooth tooth surface. The veillonellae coaggregated with only one of the strains of *S. mutans*. If the coaggregation-positive strain of *S. mutans* was allowed to colonize the teeth before infection with the veillonellae, then the veillonellae attached and colonized the tooth surface. In contrast, no colonization of veillonellae above control values was seen when the coaggregation-negative *S. mutans* was used. The validity of the animal model was supported by the results of administering another coaggregating pair, whose adherence could be inhibited by lactose (van der Hoeven et al., 1985). One member of the pair was allowed to colonize. Its partner was then added to the lactose-containing drinking water. This reduced the initial adherence of the coaggregating partner to control levels found when the partner was given alone to the animal. These results indicate that intergeneric coaggregation among oral bacteria is sensitive in vivo to similar perturbations (e.g., lactose inhibition) in the gnotobiotic animal as is found in vitro by mixing suspensions of the two partner strains (Kolenbrander, 1988a; Kolenbrander and Andersen, 1986).

Earlier studies had demonstrated that human strains of *V. parvula* (formerly *V. alcalescens*) could not establish in mono-infected germ-free mice, whereas *Streptococcus mitis* could colonize by itself (Gibbons et al., 1964). However, when inoculated with several other human strains including *S. mitis*, *V. parvula* readily became part of the oral flora, suggesting that the veillonellae adhere to primary colonizers but not directly to the host tissues. It is also possible that lactic acid

is in limiting supply in the gnotobiotic animal and that veillonellae colonize poorly in the absence of an adequate nutrient supply. In either situation veillonellae require other bacteria to establish themselves in the oral cavity.

Human Oral Cavity

Veillonellae are considered to be among the early colonizers of freshly cleaned enamel although they adhere poorly to a cleaned, human tooth surface (Liljemark and Gibbons, 1971) and to spheroidal hydroxyapatite (McBride and van der Hoeven, 1981), an extensively used model surface for adherence of oral bacteria to in vivo enamel surfaces (Clark et al., 1978). Their numbers increase in parallel with the numbers of actinomyces and after the streptococci are established (Ritz, 1967). Their inability to adhere well to smooth surfaces is in sharp contrast to their ability to recognize the surface of initial adherent cells such as *S. sanguis*, *A. naeslundii*, and *A. israelii*, which are known to bind to spheroidal hydroxyapatite (Clark et al., 1978; Clark et al., 1981; Kolenbrander and Celesk, 1983).

Veillonellae are found in proportionally very high numbers on the tongue dorsum as compared to their numbers in buccal mucosa samples or dental plaque (Liljemark and Gibbons, 1971). In this study streptomycin-resistant strains of *Veillonella* were introduced into the mouths of human volunteers for 5 minutes. Samples were taken from the tongue dorsum and tooth surface after 45 minutes and plated on streptomycin-containing agar (Rogosa et al., 1958), and the resulting colonies (number of veillonellae) were counted. The distribution of veillonellae on the two surfaces was according to their proportions found naturally.

The ecological relationship of coaggregation to colonization site was examined by testing veillonellae from subgingival plaque or the dorsum of the tongue for their ability to coaggregate with other bacteria isolated from the tongue or from subgingival plaque (Hughes et al., 1988). Results from that study indicate that bacteria occupy the same site as their coaggregation partners and suggest a direct link between coaggregation and colonization in the oral cavity.

Bacteriophage

Both temperate (Shimizu, 1968) and virulent (Totsuka, 1976) phages for human oral veillonellae have been isolated. The phage receptor for one of the veillonellophages is lipopolysaccharide (Totsuka, 1988; Totsuka and Ono, 1989).

PLASMIDS Plasmids are found in about 50% of the human oral *Veillonella* strains and most have

several plasmids whose molecular sizes range from 1.1 to 28 MDa (Arai et al., 1984). It has been suggested that fructose fermentation by some strains of *V. criceti* may be associated with plasmid-encoded genes (Mays et al., 1982).

CHAPTER 1.3.7

Syntrophomonadaceae

MARTIN SOBIERAJ AND DAVID R. BOONE

Introduction

The family Syntrophomonadaceae includes a group of anaerobes that commonly grow in syntrophic associations with molecular hydrogen (H_2)- and formate-using methanogens. The energy source for these organisms is the oxidation of carboxylic acids of four carbons or more. This oxidation is normally coupled to the production of H_2 or formate, which is consumed by methanogens or other organisms. The Syntrophomonadaceae are phylogenetically a part of the phylum of Gram-positive bacteria with low DNA G+C content. Although many of the members of this family have cell walls typical of Gram-positive bacteria, several genera *(Syntrophomonas, Thermosyntropha, Pelospora* and *Syntrophothermus*) have cell walls typical of Gram-negative bacteria, with the outer membrane of *Syntrophomonas* confirmed by electron microscopy. The division between Gram-negative and Gram-positive microbes has historically been considered an indicator of the deepest taxonomic separations (Buchanan and Gibbons, 1974; Gibbons and Murray, 1978), so it is unusual to find members of the same family containing both of these cell wall structures. Another example of this can be found in the family Acidaminococcaceae, also a family of low-G+C Gram-positive bacteria, that contains some genera which have ultrastructures typical of Gram-negative bacteria.

In general, the members of this family are unified by their common environmental association with methanogens, and this association makes their metabolic capabilities possible. These bacteria are found predominantly in anaerobic environments where organic matter is completely degraded to methane and carbon dioxide. In such environments, oxygen, sulfate, nitrate, nitrite, and ferric ions are not readily available as electron acceptors for the degradation of organic matter; thus methanogenesis is the dominant process. Within these ecosystems, members of the family are found in syntrophic associations with methanogens.

Whereas most of the members of Syntrophomonadaceae grow by syntrophically oxidizing monocarboxylic acids, *Pelospora* differ. They do not require syntrophy (they ferment succinate or glutarate) and they are found in nonmethanogenic environments. The other members of this family obtain their energy for growth from the degradation of a variety of fatty acids ranging from four to eighteen carbons in length. The oxidation of these compounds is thermodynamically unfavorable unless the products (H_2 and/or formate) are maintained at low concentrations by the action of the syntrophic partner, such as a methanogen (Table 1). When the methanogenic partner is absent, the concentrations of H_2 and formate rapidly increase to values that thermodynamically inhibit fatty-acid oxidation. Therefore, syntrophic bacteria in their natural environment are obligately dependent on the activity of the methanogens. There are no alternate fermentative pathways for energy production from compounds such as butyrate. When these organisms first were isolated, no mechanism other than syntrophy was known that would allow their growth, and they were called "obligate proton-reducing acetigens" (McInerney et al., 1979). Since that time, butyrate-degrading syntrophs were found capable of growth on crotonate (Beaty and McInerney, 1987). This eliminates the need for a H_2/formate-using bacterium, allowing their growth as pure cultures.

Phylogeny and Taxonomy

Sequence analysis of the 16S rDNA genes (Fig. 1) indicates that the family Syntrophomonadaceae is monophyletic, and separate from the genera *Moorella* and *Thermoanaerobacter*. The family contains five genera, most of which are also monophyletic. However, the genus *Syntrophomonas* appears to be paraphyletic. In 84 of 100 bootstrap trees, *Syntrophomonas wolfei*, the type species of *Syntrophomonas*, is more closely related to *Syntrophospora bryantii* and *Pelospora glutarica* than it is to *Syntrophomonas sapovorans*. The phylogenetic distance between *Syntrophomonas sapovorans* and *Syntrophomonas wolfei* is sufficient (sequence similarity

Table 1. The major reactions involved in the anaerobic degradation of mono- and dicarboxylic acids by members of the family Syntrophomonadaceae.

Reactions	Free energy yield $\Delta G^{o\prime}$ (kJ/mol)
Some reactions of H$_2$/formate-using bacteria	
Methanogens	
$4H_2 + HCO_3^- + H^+ \leftrightarrow CH_4 + 3H_2O$	−135.6
$4HCO_2^- + H_2O + H^+ \leftrightarrow CH_4 + 3HCO_3^-$	−130.4
Sulfate-reducing bacteria	
$4H_2 + SO_4^{2-} + H^+ \leftrightarrow HS^- + 4H_2O$	−151.0
Some reactions of members in the family Syntrophomonadaceae:	
Without H$_2$/formate-using bacterium	
$CH_3CH_2CH_2COO^- + 2H_2O \leftrightarrow 2CH_3COO^- + H^+ + 2H_2$	+48.1
$CH_3CH_2CH_2CH_2COO^- + 2H_2O \leftrightarrow CH_3COO^- + CH_3CH_2COO^- + H^+ + 2H_2$	+48.1
$2CH_3HC=CH—COO^- + 2H_2O \leftrightarrow 2CH_3COO^- + CH_3CH_2CH_2COO^- + H^+$	−101.9[a]
$^-OOCCH_2CH_2COO^- + H_2O \leftrightarrow CH_3CH_2COO^- + HCO_3^-$	−20.5[b]
With H$_2$/formate-using bacterium	
$2CH_3CH_2CH_2COO^- + HCO_3^- + H_2O \leftrightarrow 4CH_3COO^- + CH_4 + H^+$	−39.4
$2CH_3CH_2CH_2CH_2COO^- + HCO_3^- + H_2O \leftrightarrow 2CH_3COO^- + 2CH_3CH_2COO^- + CH_4 + H^+$	−39.4
$2CH_3CH_2CH_2COO^- + SO_4^{2-} \leftrightarrow 4CH_3COO^- + HS^- + H^+$	−54.8
$2CH_3CH_2CH_2CH_2COO^- + SO_4^{2-} \leftrightarrow 2CH_3COO^- + 2CH_3CH_2COO^- + HS^- + H^+$	−54.8

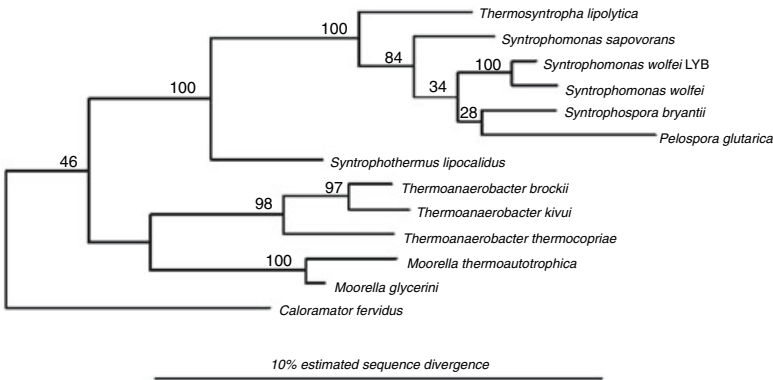
[a]Most members of the family Syntrophomonadaceae grow on crotonate in pure culture.
[b]*Pelospora glutarica* is the only member of the Syntrophomonadaceae family that is capable in growing on succinate.
Data compiled from Schink (1997) and Thauer et al. (1977), or were calculated from data therein.


Fig. 1. Phylogenetic tree for members of the Syntrophomonadaceae family and related organisms based upon 16S rDNA sequences. The GenBank accession numbers for the 16S rRNA sequences reported in this paper are as follows: *Thermosyntropha lipolytica* DSM 11003[T] {X99980}, *Pelospora glutarica* WoGI3[T] {AJ251214}, *Syntrophospora bryantii* DSM 3943[T] {M26491}, *Syntrophomonas sapovorans* DSM 3441[T] {AF022249}, *Syntrophomonas wolfei* subsp. *wolfei* DSM 2245[T] {M26492}, *Syntrophomonas wolfei* LYB {AF022248}, *Syntrophothermus lipocalidus* TGB-C1[T] {AB021305}, *Moorella thermoautotrophica* DSM 1974[T] {X77849}, *Moorella glycerini* DSM 11254[T] {482327}, *Caloramator fervidus* ATCC 43204[T] {L09187} *Thermoanaerobacter thermocopriae* IAM 13577[T] {L09167}, *Thermoanaerobacter brockii* HTD4[T] {L09165}, and *Thermoanaerobacter kivui* DSM 2030[T] {L09160}. Sequences were manually aligned and checked for secondary structure to ensure only homologous regions were compared. The aligned sequences included 1336 bases, but a mask (Page and Holmes, 1998) was employed that reduced the number of nucleotides that were compared to 1197. Evolutionary distances were computed from pairwise similarities by employing the correction of Jukes and Cantor (1969). The program ARB was used for analyzing and assembling sequence data. The phylogenetic trees were constructed by using the maximum-likelihood analysis with fastDNAml (Olsen et al., 1994). Bootstrap values were determined for the maximum-likelihood trees with 100 replicates.

determined from a binary comparison of 16S rDNA genes of these two species is 92%, Matthies et al., 2000, or 95% in our masked alignment) to support the proposal of a separate genus within the family for *Syntrophomonas sapovorans*.

Habitat

Members of the family Syntrophomonadaceae are predominantly found in methanogenic environments in syntrophic associations with methanogens. In such environments, various electron acceptors are not readily available and methanogenesis is the dominant metabolism (McInerney, 1986). In such environments, primary fermentative bacteria degrade organic matter to extracellular products including H_2, formate and acetate. Each of these is consumed directly by methanogens in the production of methane and carbon dioxide. Other products of the primary fermentative bacteria, such as monocarboxylic acids, cannot be used directly by methanogens. Rather, these compounds are degraded by syntrophic interactions between methanogens and syntrophs such as Syntrophomonadaceae. The important syntrophs that degrade fatty acids between 4 and 18 carbons are in this family, whereas those that degrade propionate (3 carbons) belong in the genera *Syntrophobacter* (Boone and Bryant, 1980) or *Smithella* (Liu et al., 1999).

Thus, syntrophic bacteria represent an essential trophic level that convert the fatty acids produced by fermentative bacteria from complex organic matter to methanogenic substrates such as acetate, H_2 and formate. Examples of such environments include sewage digestors, waterlogged soils, aquifers and sediments. Syntrophic bacteria are generally found where organic matter is degraded and inorganic electron acceptors are absent. In shallow marine sediments, sulfate reduction is the dominant metabolism, and many fatty acids may be degraded directly by sulfate-reducing bacteria. However, syntrophy does still occur in such environments (Stieb and Schink, 1985; Tschech and Schink, 1985a; 1985b).

Syntrophomonadaceae can also grow in nonmethanogenic anoxic environments: *Pelospora glutarica* is able to grow on compounds such as succinate in the absence of a syntrophic partner (Matthies et al., 2000).

Isolation

The species of Syntrophomonadaceae are extremely sensitive to oxygen. Stringent anaerobic techniques as described by Hungate (1969) or modifications of those techniques (Sowers and Noll, 1995) are used to prepare anaerobic media and solutions for cultivation. These methods usually involve the replacement of air with oxygen-free gases and the addition of strong chemical reducing agents such as cysteine, mercaptoethanesulfonate, and sodium sulfide (alone or in combinations) to maintain low oxidation-reduction potentials.

Selective Enrichment

Syntrophomonadaceae often grow in the presence of large numbers of heterotrophic bacteria. Therefore, it is difficult to isolate them directly without a preliminary enrichment step. Fatty acid-degrading syntrophs can be selectively enriched in a reduced medium that contains a fatty acid as electron donor and carbon dioxide as electron acceptor. Oxygen, ferric iron, sulfate, sulfur, nitrate, and nitrite should be avoided because such ions would support the growth of nonsyntrophic bacteria. The culture must contain a suitable H_2-utilizing methanogen to maintain low concentrations of hydrogen and make the degradation of fatty acids thermodynamically favorable. Such methanogens may be present in starting sample material or a suitable methanogen may be added.

Enrichment media, like the media for cultivation of pure cultures of syntrophs, are usually buffered by carbon dioxide and bicarbonate to a pH similar to that of the environment, and contain inorganic ions. A small amount of organic compounds that may include possible growth factors is often added. Rumen fluid (2–20% of volume) or yeast extract and peptones (0.05–0.5 g) are sometimes added for this purpose. However, additions of organic matter other than the syntrophic substrate may support the growth of nonsyntrophic bacteria, so these should be minimized. Additionally, the use of organic reducing agents should be avoided. The use of cysteine or mercaptoethanesulfonate may enrich for bacteria that degrade these compounds. The catabolic substrate is added at a concentration of about 1–2 g per liter. Certain species of the Syntrophomonadaceae family can be selected for by addition of a specific substrate. For instance, *Syntrophothermus lipocalidus* uses isobutyrate, which no other species in the family can metabolize.

To obtain numerically important syntrophs from an environment, dilutions of the original sample are inoculated into enrichment media and incubated. After a suitable time of incubation, the highest dilution (smallest inoculum) that produced a successful enrichment culture should contain the syntrophic organism that was most numerous in the original sample. This enrichment culture may be used as inoculum to isolate syntrophic cocultures.

Growth Media and Solutions

A large number of anoxic media have been formulated for the growth of fatty-acid-degrading syntrophic bacteria. Many are found in the original species description papers cited throughout this chapter. We describe only a generalized medium here. Optimal growth of these microorganisms may require modification of the concentrations of some of the components or special additions. The following basal medium can be used to cultivate the various species of the family Syntrophomonadaceae in cocultures by changing the catabolic substrate added to the medium (McInerney et al., 1979):

Basal Medium

Mineral solution (see below)	5%
Trace metal solution (see below)	0.1%
Vitamin solution (see below)	0.5%
Rumen fluid	2%
Sulfide-reducing solution (see below)	2%
Coenzyme M	0.05%
Resazurin	0.0001%
Substrate	0.2%

The bicarbonate medium is prepared by dissolving NaOH (3.5 g per l liter) in oxygen-free distilled water and equilibrating the preparation with 100% carbon dioxide. All the constituents above (except the sulfide-reducing solution) are added at the indicated final concentrations in percent (v/v), and the pH of the medium is adjusted to 7.2–7.4 under a stream of oxygen-free N_2 and CO_2 (4 : 1) gas mixture. The medium is then dispensed (under continuous stream of the above anoxic gas mixture) into 27-ml serum tubes fitted with butyl rubber stoppers, sealed, and autoclaved (121°C, 20 min). The medium is cooled, and before use, the sulfide-reducing solution is added individually to each tube. For solid media, purified agar (18 g per l liter) is added to the medium and is maintained in suspension by utilizing a magnetic stirrer as it is dispensed into serum tubes.

Mineral Solution

KH_2PO_4	10.0 g
$MgCl_2 \cdot 6H_2O$	6.6 g
NaCl	8.0 g
NH_4Cl	8.0 g
$CaCl_2 \cdot 2H_2O$	1.0 g
Distilled water	1 liter

Trace Metal Solution

Nitrilotriacetic acid	2.0 g
$MnSO_4 \cdot H_2O$	1.0 g
$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	0.8 g
$CoCl_2 \cdot 6H_2O$	0.2 g
$ZnSO_4 \cdot 7H_2O$	0.2 g
$CuCl_2 \cdot 2H_2O$	0.02 g
$NiCl_2 \cdot 6H_2O$	0.02 g
$Na_2MoO_4 \cdot 2H_2O$	0.02 g
Na_2SeO_4	0.02 g
Na_2WO_4	0.02 g
Distilled water	1 liter

To prepare the trace metal solution, dissolve the nitrilotriacetic acid in 800 ml of distilled water and adjust the pH to 6.0 with KOH. Then dissolve the minerals and bring the volume to 1 liter.

Vitamin Solution

Nicotinic acid	20 mg
Cyanocobalamin	20 mg
Thiamin · HCl	10 mg
p-Aminobenzoic acid	10 mg
Pyridoxine · HCl	50 mg
Calcium pantothenate	5 mg
Distilled water	1 liter

The substrate is added at a concentration, which will not inhibit growth. For short-chain fatty acids, a concentration of 20 mM is used, while lower concentrations (>5 mM) are used for long-chain fatty acids. Higher concentrations of long-chain fatty acids require the supplementation of equimolar calcium chloride into the medium.

For growth of lipolytic, alkalitolerant, fatty acid degrading bacteria, the medium is prepared under a nitrogen atmosphere (pH 8.2) and may be supplemented with olive oil (20 ml per liter) and yeast extract (5 g per liter) rather than rumen fluid (Svetlitshnyi et al., 1996).

Culturing H_2-Utilizing Microorganisms

Several mesophilic anaerobes that syntrophically oxidize fatty acids have been isolated in cocultures with H_2-utilizing strains such as *Desulfovibrio* and *Methanospirillum hungateii*. *Syntrophomonas wolfei* subsp. *wolfei* was the first documented mesophilic strain isolated in coculture with a methanogen or a sulfate-reducer. In addition, thermophilic fatty acid-oxidizing bacteria such as *Thermosyntropha lipolytica* and *Syntrophothermus lipocalidus* have been obtained in cocultures with strains of *Methanobacterium thermautotrophicum* or related strains. Thus, choosing the appropriate H_2-utilizing microbe is essential to obtain cocultures of syntrophic bacteria. Fatty acid β-oxidation tends to be thermodynamically more favorable when it is coupled to H_2 utilization by a sulfate-reducer rather than by a methanogen because the reduction of sulfate to sulfide by H_2 is thermodynamically more favorable than the reduction of CO_2 to CH_4 by H_2. Thus, sulfate-reducing, syntrophic cocultures grow faster and to higher yields than the methanogenic cocultures, but it may be easier later to obtain axenic cultures when methanogens are used as partners.

The basal medium above without the addition of a substrate may be sufficient for the growth of the H_2-utilizing microorganisms. A gas mixture of H_2 and CO_2 (4 : 1) is added after dispensing and autoclaving the medium. The culture tubes are pressurized to 100 kPa above atmospheric pressure. For the growth of H_2-utilizing sulfate-

reducing bacteria, the basal medium is supplemented with 3 g of Na_2SO_4.

During growth on H_2 and CO_2, methanogens quickly consume gas to produce CH_4 (5 mol of gas: 1 mol of CH_4); therefore a negative pressure develops in the culture tubes. Additionally, as the partial pressure of CO_2 decreases, the medium becomes alkaline, which may inhibit growth and cause cell lysis. To minimize these problems, the volume of the headspace should be pressurized periodically throughout the growth period with N_2 and CO_2 (4 : 1 vol/vol).

Isolation of Cocultures and Axenic Cultures

Serial ten-fold dilutions of the enrichment culture are prepared while avoiding exposure of the cultures to O_2, and a culture of the H_2-using partner organism is added to each tube. These tubes are mixed and inoculated into molten anaerobic roll-tube media (45°C) with and without the catabolic substrate. The roll tubes are rolled to coat the agar on the inside of the tube and incubated at an appropriate temperature. Colonies may take several months to develop, and result in syntrophic cocultures. Colonies that appear within the first few weeks of incubation are probably growing too fast to be syntrophic cocultures, and these may be marked so that late-forming colonies can be easily distinguished. Syntrophic colonies contain a mixture of the syntroph and its partner, so when a methanogen is used as the syntrophic partner, the syntrophic colonies may be distinguished by the presence of the methanogens' epifluorescence. Colonies are selected, picked, and inoculated into enrichment medium. These cultures are immediately diluted and re-inoculated into roll-tube media together with the syntrophic partner (as described above). This process is repeated until a single colony type remains. At this point, the culture contains a single strain of syntrophic bacteria plus the syntrophic partner that was selected.

To obtain axenic cultures from these cocultures, it is necessary to find a suitable substrate that supports the growth of the syntroph without its partner. Crotonate has been successfully used for butyrate-degrading bacteria. The coculture is grown in medium with crotonate as the sole catabolic substrate; this enriches for the butyrate-degrading syntroph and limits the growth of the methanogen. A pure culture of the syntroph may be obtained by serial dilution of the culture (with higher dilutions having the syntroph present but no methanogens) or by preparing roll tube media with crotonate to obtain pure colonies of the syntroph.

Maintenance Procedures

Pure cultures or cocultures may be stored for several weeks as liquid suspensions, or suspensions can be frozen in the presence of cryoprotectant (5% glycerol) by cooling at 1°C/min and stored at liquid nitrogen temperatures (Boone, 1995), or cultures can be maintained by regular subculturing (Hippe, 1984).

Identification

Syntrophomonadaceae includes organisms that oxidize monocarboxylic acids with 4–18 carbons syntrophically, and are unable to use alternate electron acceptors such as sulfate. The descriptions below include some of the most important and distinctive characteristics of the genera, and more detailed descriptions may be found in the original citations, which are included in the footnotes to Table 2. Whenever possible, the descriptions of the genera summarize the properties of all the described species as well as the type species. The description of many of the species of this family is based on a single strain. Additionally, caution must be exercised in the evaluation of results from different laboratories because many of the growth descriptions depend greatly upon experimental conditions. In particular, variation in growth optima may occur depending on whether growth is measured by turbidity, cell counts, methane formation, growth rate, or growth yield.

Pelospora

Only one species, the type species *Pelospora glutarica*, has been described. The ability to grow on dicarboxylic acids such as glutarate, methylsuccinate, and succinate, without syntrophic interactions is the most distinctive and perhaps the most important phenotypic feature of *Pelospora*. No other genus in the family metabolizes such substrates either alone or in syntrophic associations. The rod-shaped cells of *Pelospora* stain Gram negative, are motile by one subpolar flagellum, and form terminal endospores. This mesophilic organism grows most rapidly at pH values of 7.1–8.2 and salt concentrations lower than 100 mM.

Syntrophomonas

Members of the genus *Syntrophomonas* contain Gram-negative, nonsporeforming, weakly motile, rod-shaped cells. These cells possess 2–8 flagella that are laterally inserted in a linear fashion on the concave side of the cell about 130 nm or more apart. The species and subspecies of *Syntrophomonas* are differentiated from each

Table 2. Phenotypic characteristics of members in the family Syntrophomonadaceae.

Characteristic	Pelospora	Syntrophomonas	Syntrophospora	Syntrophothemus	Thermosyntropha

Abbreviations: +, present in all species; −, absent in all species; ND, not determined; and PABA, *p*-aminobenzoic acid.
[a]This genus weakly degrades pyruvate in pure culture.
[b]Most species within this genus can grow in pure culture on crotonate, however, *Syntrophomonas sapovorans* cannot.
[c]Some species in this genus can only degrade fatty acids up to C$_{12}$.
[d]Some species in this genus cannot degrade oleate in syntrophic co-cultures.
[e]Some species in this genus cannot degrade linoleate in syntrophic co-cultures.
[f]The B-vitamins include biotin, thiamine, cyanocobalamin, and lipoic acid.
Data compiled from: Beaty and McInerney (1990); Lorowitz et al. (1989); Matthies et al. (2000); McInerney et al. (McInerney et al., 1979, McInerney et al., 1981); Roy et al. (1986); Sekiguchi et al. (2000); Stieb and Schink (1985); Svetlitshnyi et al. (1996), and Zhao et al. (Zhao et al., 1990, Zhao et al., 1993).

other on the basis of their substrate utilization patterns (Table 2). *Syntrophomonas wolfei* contains two subspecies, one of which (*S. wolfei* subsp. *wolfei*) syntrophically degrades normal saturated fatty acids with 4–8 carbons and isoheptanoate; whereas *S. wolfei* subsp. *saponavida* syntrophically degrades normal saturated fatty acids with 4–18 carbons and the *iso*-fatty acids isoheptanoate and longer. All species and subspecies of *Syntrophomonas* grow in pure culture on crotonate and are stimulated by the addition of B vitamins, amino acids, or rumen fluid. Most

rapid growth is observed at 35–37°C and at near neutral pH.

Syntrophospora

The rod-shaped cells of *Syntrophospora* have ultrastructure similar to that of Gram-positive bacteria and are nonmotile. The most distinctive feature of this genus is that the cells form oval, terminal endospores during growth on fatty acids. Saturated fatty acids (butyrate and longer) are β-oxidized to acetate and H$_2$ (or also propi-

onate in the case of odd-numbered acids) in syntrophic cooperation with H_2-utilizing microorganisms. *Syntrophospora* grows in pure culture on crotonate. Most rapid growth occurs at near neutral pH and at 34°C. The type strain of this genus is *Syntrophospora bryantii*.

Syntrophothermus

The rod-shaped cells of *Syntrophothermus* stain Gram-negative, are weakly motile, and non-sporeforming. This organism can grow in pure culture only on crotonate. In syntrophic cooperation with H_2-utilizing microorganisms, cells of *Syntrophothermus* can metabolize saturated fatty acids with 4–10 carbon atoms by β-oxidation. The ability to degrade isobutyrate by isomerization to butyrate in syntrophic cooperation with an H_2-utilizing organism is the most distinguishing phenotypic feature of *Syntrophothermus*. Most rapid growth is observed at 55°C and at near neutral pH. *Syntrophothermus lipocalidus* is the type species of the genus.

Thermosyntropha

Thermosyntropha lipolytica is the type, and so far, the only species in this genus. The ability to hydrolyze triglycerides and utilize the liberated short- and long-chain fatty acids in syntrophic cooperation with an H_2-utilizing methanogen is the most distinctive and perhaps the most important phenotypic feature of *Thermosyntropha*. This organism can be cultured on a number of substrates (refer to Table 2), whereas most species in the family can only grow on crotonate in pure culture. Oleate, linoleate, and saturated fatty acids (butyrate up to stearate) are metabolized in cocultures with H_2-utilizing microorganisms. The rod-shaped cells of *Thermosyntropha* stain Gram negative, are nonmotile, and non-sporeforming. This organism grows mostly rapidly at pH 8.1–8.9 and at temperatures between 60 and 66°C.

Biochemical and Physiological Properties

Biochemistry of Syntrophic Butyrate Metabolism

Fermenation of butyrate to acetate and H_2 is an endergonic reaction (see Table 1) under standard conditions. Degradation of butyrate is feasible only at a low H_2 partial pressure (below 10^{-4} to 10^{-5} atm; McInerney et al., 1981; Schink, 1997), which can be maintained by methanogenic bacteria. The pathway of butyrate oxidation in syntrophic butyrate-oxidizing bacteria has been

tentatively elucidated with *Syntrophomonas wolfei*. The pathway proceeds through classical fatty acid β-oxidation which involves seven steps (Wofford et al., 1986). Step one involves the activation of butyrate via acetyl-CoA by CoA-transferase (Fig. 2, step 1). This is followed by the oxidation of butyryl-CoA to crotonyl-CoA via the enzyme acyl-CoA dehydrogenase (Fig. 2, step 2). The electron transfer is mediated by the flavin-adenine dinucleotide (FAD) prosthetic group of the enzyme. The formation of L(+)-3-hydroxybutyryl-CoA is catalyzed by the enoyl-CoA hydratase, which incorporates a water molecule into crotonyl-CoA (Fig. 2, step 3). Then L(+)-3-hydroxybutyryl-CoA undergoes dehydrogenation to acetoacetyl-CoA via the L(+)-3-hydroxybutyryl-CoA dehydrogenase enzyme (Fig. 2, step 4). This electron transfer is mediated by the coenzyme NAD^+. The fifth step of β-oxidation is the thiolase reaction (Fig. 2, step 5), which yields two acetyl-CoA molecules. This reaction proceeds through a Claisen ester cleavage, with the first two carbons released as acetyl-
Fig. 2. Pathway of butyrate degradation by *Syntrophomonas wolfei*.

CoA and the second two carbons forming an enzyme-thioester intermediate. This acetyl group is cleaved with CoA by a displacement reaction, generating the second acetyl-CoA molecule. In step 6 (Fig. 2, step 6), acetyl-CoA is converted to acetyl-PO_4^{2-} by the enzyme phosphotransacetylase, via a displacement reaction involving inorganic phosphate. The terminal reaction, catalyzed by acetate kinase, yields an acetate molecule and one ATP by means of substrate-level phosphorylation (Fig. 2, step 7).

The proposed butyrate degradation pathway suggests that for every mole of butyrate oxidized to acetate one mole of ATP is synthesized. Thauer and Morris (1984) proposed that some of the ATP produced from substrate-level phosphorylation is used to drive the reverse electron flow, via proton motive force (Wallrabenstein and Schink, 1994), associated with H_2 production from the reaction mentioned above (Fig. 2, step 2). This reverse electron transport would be necessary for the production of H_2 from FAD. Such reversed electron transport processes have been observed with cell suspensions of *Methanosarcina barkeri* (Bott and Thauer, 1989) and *Desulfovibrio vulgaris* (Pankhania et al., 1988). This is consistent with the amount of ATP anticipated from thermodynamic calculations, which indicate that the free energy available from the reaction can be as low as −20 kJ/mol (Thauer et al., 1977).

Biochemistry of Long-Chain Fatty Acid Metabolism

Syntrophic degradation of long-chain fatty acids probably involves several rounds of β-oxidation with the concomitant release of electrons as H_2 via a reversed electron transport, analogous to the pathway described for syntrophic butyrate degradation above.

Biochemistry of Crotonate Metabolism

Members of the family Syntrophomonadaceae are capable of growing in pure culture, without a syntrophic partner, when grown on crotonate (Beaty and McInerney, 1987; McInerney and Wofford, 1992). The use of crotonate as an energy source bypasses an unfavorable step, the oxidation of butyryl-CoA to crotonyl-CoA (Fig. 2, step 2) in the butyrate degradation pathway. Therefore, the bacterium generates ATP without the dependence upon interspecies electron transfer because crotonate is metabolized by a disproportionation mechanism wherein part of the substrate is oxidized to acetate and the remainder is reduced to butyrate or longer chain fatty acids (Beaty and McInerney, 1987;

McInerney and Wofford, 1992). In addition, it was reported that *Syntrophomonas wolfei* contains a *c*-type cytochrome, which may make it possible for the organism to produce ATP not only by substrate-level phosphorylation, but also through the use of an electron transport-linked reduction of crotonate (McInerney and Wofford, 1992). Localization experiments revealed that the *c*-type cytochrome is situated at the membrane and is reduced by H_2 (M. J. McInerney and N. Q. Wofford, unpublished data).

The pathway of crotonate degradation was elucidated in *S. wolfei* (McInerney and Wofford, 1992). For each crotonate that is oxidized to two acetates, another crotonate is reduced to butyrate. In the first step of the oxidation of crotonate, crotonate is activated to crotonyl-CoA by a CoA transferase. The activity of this enzyme was not present in cell-free extracts prepared from butyrate-grown cells. This suggests that the crotonate CoA transferase has an altered substrate specificity or is a new enzyme that is synthesized when crotonate is present as substrate. This is followed by the oxidation of crotonyl-CoA to acetate according to the steps 3–5 of the butyrate degradation pathway (Fig. 2). This oxidation generates one pair of electrons on NADH and one ATP. For each crotonate thus oxidized, a second crotonate is reduced to butyrate. The second crotonate is converted to crotonyl-CoA as described above, and this crotonyl-CoA is reduced by the reverse of steps 2 and 1 (Fig. 2), with $FADH_2$ the electron donor. This reductive branch does not generate ATP directly, but electrons from NADH generated from the oxidative branch (steps 3–5) are passed down to $FADH_2$ for use in reducing crotonyl-CoA, and this electron transfer can be coupled to the synthesis of a fraction of an ATP.

CHAPTER 2.1

The Cyanobacteria—Isolation, Purification and Identification

JOHN B. WATERBURY

The oxygenic photosynthetic bacteria comprise two groups, the cyanobacteria and the prochlorophytes, that are distinguished by their photosynthetic pigment composition. The cyanobacteria contain chlorophyll *a* and phycobiliproteins as their primary photosynthetic pigments (see The Cyanobacteria—Ecology, Physiology and Molecular Genetics in this Volume) while the prochlorophytes contain chlorophylls *a* and *b* and lack phycobiliproteins (see The Genus Prochlorococcus in this Volume).

The cyanobacteria are morphologically and developmentally one of the most diverse groups of prokaryotes. They range from simple unicellular forms that reproduce by binary fission to complex filamentous forms that possess a variety of highly differentiated cell types. Some of the filamentous forms are capable of true branching, and some are even truly multicellular, as the result of cellular differentiation and functional specialization between vegetative cells and heterocysts, the sites of oxygenic photosynthesis and dinitrogen fixation, respectively.

Traditionally this group of phototrophic prokaryotes has been classified as a group of algae under the aegis of the Botanical Code (Stafleu et al., 1972). Phycologists have developed a system of classification for these organisms based on their morphological, developmental, and ecological characters, as determined not on pure cultures but on natural samples. This system, which contains about 150 genera and 1000 species, has proven to be successful for the classification of cyanophytes in natural material but is inadequate in many instances for the classification of cyanobacteria maintained in axenic culture.

During the last 25 years, following the unequivocal demonstration of the prokaryotic nature of these organisms, a number of bacteriologists have become interested in and have applied traditional microbiological techniques to the study of cyanobacteria. As a result of these studies there are currently several hundred isolates of cyanobacteria maintained in pure culture. These isolates include representatives of many, but certainly not all, of the major groups of cyanobacteria described in the botanical literature.

The classification of cultured cyanobacteria has been problematic. It was hoped that phenotypic and genotypic characters, made accessible by the availability of pure cultures, would facilitate the classification of the group. However, until recently, this, in large part, had not proven to be the case. As in the traditional botanical taxonomic treatments, morphological and developmental features form the bases for the description of taxa at the level of genera and above (Castenholz, 1989a, 1989b, 1989c; Rippka, 1988b; Waterbury, 1989). Exceptions occur among some unicellular cyanobacteria that lack adequate morphological and developmental complexity to permit genera to be defined by these criteria alone (Waterbury and Rippka, 1989). However, because of the importance of structural and developmental characters for the classification of both field and cultured material, it will be possible for the system of classification currently being developed for the cyanobacteria, under the aegis of the Bacteriological Code (Lapage, 1975) to represent, to a large degree, a logical extension and refinement of the classical botanical system.

Major Groups of Cyanobacteria

The cyanobacteria studied in pure culture are currently placed in five orders (Castenholz, 1989a, 1989b, 1989c; Waterbury, 1989; Waterbury and Rippka, 1989) described below that correspond closely to the five groups (Sections) used by Stanier and his collaborators (Rippka, 1988b; Rippka et al., 1979, 1981b).

Chroococcales

Members of the order Chroococcales are unicellular cyanobacteria that reproduce by binary fission or budding. Division occurs in one, two, or three planes at right angles to one another or in irregular planes. Cells can range in size from 0.5–30 μm and can occur as single cocci and rods or as cell aggregates. The form and size of cell

---

This chapter was taken unchanged from the second edition.

aggregates depend on the planes of division and on the presence of extracellular slime or structured sheaths that hold the cells together.

Pleurocapsales

All members of the order Pleurocapsales reproduce by multiple fission, a feature that distinguishes them from other cyanobacteria. Pleurocapsalean cyanobacteria range from unicellular forms that divide exclusively by multiple fission to forms that produce cell aggregates by vegetative binary fission. Such cell aggregates range in complexity from groups of a few cells to complex pseudofilamentous cell assemblages. Following aggregate formation, some cells in the assemblage undergo multiple fission and release unicellular structures called baeocytes. Baeocytes immediately initiate growth leading to the next vegetative cell cycle.

Oscillatoriales

The order Oscillatoriales includes all the undifferentiated filamentous cyanobacteria. Cell division occurs by binary fission in one plane at right angles to the long axis of the trichomes. Reproduction occurs by trichome fragmentation or by the production of undifferentiated hormogonia released from the ends of trichomes. Although cell size and shape and trichome length vary widely among members of the order, within individual organisms, cell diameter and cell shape are quite constant. Cell diameters vary from 0.5–100 µm, and cell dimensions range from being much longer than wide (rod-shaped) to being much wider than long (disk-shaped).

Nostocales

The order Nostocales includes filamentous cyanobacteria that are capable of cell differentiation and that divide by binary fission in one plane at right angles to the long axis of the trichomes. Differentiation may result in the production of several types of specialized cells: 1) heterocysts; 2) akinetes; 3) specialized reproductive trichomes (hormogonia) whose cells are morphologically distinguishable from vegetative cells; and 4) tapered trichomes, formed usually in response to a nitrogen gradient caused by terminally located heterocysts.

Stigonematales

Members of the order Stigonematales are filamentous cyanobacteria capable of the same degree of cellular differentiation as members of the Nostocales, but in addition they are able to divide by binary fission in multiple planes. The resulting thalli may display true branching and possess both uniseriate and multiseriate trichomes.

Phylogeny

Until the advent of molecular sequencing it was not possible to quantitatively determine phylogenetic relationships among prokaryotes. Woese and his colleagues have revolutionized the study of prokaryotic phylogeny using ribosomal RNA sequence analyses. Using both partial and complete 16S rRNA sequences, Woese has divided the prokaryotes into two major subgroups, the archaebacteria and the eubacteria (Woese, 1987). The cyanobacteria, as well as the chloroplasts of higher plants and the prochlorophytes (Turner et al., 1988) all fall within a common lineage that comprises one of 10 major eubacterial taxa (Woese, 1987). At the time of Woese's review, the cyanobacteria were circumscribed by eight rRNA sequences from isolates representing only a minor portion of cyanobacterial diversity (Bonen et al., 1979).

A more detailed study by Giovannoni et al. (1988) analyzed the 16S rRNAs of 29 strains of cyanobacteria, including key reference strains from each of the five orders. This study permitted its authors to delineate the major phylogenetic patterns of the cyanobacteria currently available in pure culture. They found that the rRNA sequence diversity within the cyanobacteria is considerably less than the diversity that separates other major eubacterial taxa, indicating that relatively close phylogenetic relationships underlie the extensive morphological diversity that occurs within the cyanobacteria. In addition, many of the cyanobacterial lineages have similar branching depths (Fig. 1), indicating that the modern groups arose from an expansive radiation. The combination of relatively small sequence diversity and the fanlike radiation of the lineages makes it impossible at present to determine the precise branching orders of many of the cyanobacterial groups. Members of the Chroococcales and the Oscillatoriales are dispersed throughout the phylogenetic tree, indicating that these two orders, as presently constituted, do not represent coherent evolutionary lineages (Fig. 1). Members of the Pleurocapsales fall within a single lineage indicating that reproduction by multiple fission is of monophyletic origin (Fig. 1). Members of the Nostocales and Stigonematales fall within a single coherent lineage, suggesting that the ordinal separation of these two groups may be unwarranted (Fig. 2).

Physiological Properties Relating to Habitat Diversity

Cyanobacteria possess properties that allow them to successfully inhabit and often dominate a wide variety of illuminated habitats. Their dominant mode of nutrition is photoautotrophy,
Fig. 1. Rooted-tree topology illustrating evolutionary relationships among 16S rRNAs from cyanobacteria. Evolutionary distances are proportional to the horizontal component of segment length in this representation. *A. tumefaciens, B. subtilis,* and *P. testosteroni* 16S rRNA sequences were used to locate the root. Only one heterocystous cyanobacterium, *Anabaena* sp. strain PCC 7122, is included in this tree. The scale is in units of fixed point mutations per sequence position. (From Giovannoni et al., 1988.)
Fig. 2. Rooted-tree topology illustrating evolutionary relationships among 16S rRNAs from heterocystous cyanobacteria. See the caption of Fig. 1 for explanation. (From Giovannoni et al., 1988.)

using a photosynthetic apparatus that carries out oxygenic plantlike photosynthesis with chlorophyll *a* as the primary photosynthetic pigment and phycobiliproteins as auxilliary light-harvesting pigments (Bryant, 1986; van Liere and Walsby, 1982; see also The Cyano bacteria—Ecology, Physiology and Molecular Genetics in this Volume). Some cyanobacteria are capable of switching from oxygenic photosynthesis to anoxygenic bacterial-type photosynthesis when they occur in environments where hydrogen sulfide is present at relatively high concentrations (3 mM) (Cohen et al., 1986; Padan and Cohen, 1982).

Cyanobacteria can exploit niches varying from very dimly lit caves to salt-marsh algal mats exposed to full sunlight (Wyman and Fay, 1987). Adaptations to light include the ability to alter their photosynthetic apparatus in response to light quantity and quality by changing the surface area of their photosynthetic thylakoids, and by changing the size and phycobiliprotein composition of their phycobilisomes (Cohen-Bazire and Bryant, 1982; Glazer, 1981; Kana and Glibert, 1987a, 1987b). In addition, some of the phycoerythrin-containing cyanobacteria can adapt to changes in light quality by complementary chromatic adaptation, a process in which phycobiliprotein synthesis is under light-wavelength control (Tandeau de Marsac, 1977, 1983). Cyanobacteria also protect themselves from growth-inhibiting light intensities with a variety of pigments that adsorb harmful radiation (e.g., carotenoids and xanthophylls) and possibly through structures that scatter light (e.g., gas vacuoles and calcified sheaths) (van Liere and Walsby, 1982). Finally, some cyanobacteria have the ability to position themselves in a light field through buoyancy regulation or active motility. Cyanobacteria derive buoyancy from the possession of gas vesicles and are thought to regulate their position in a water column through the use of one or more of three mechanisms: 1) regulation of gas vesicle formation; 2) gas vesicle collapse resulting from high cell turgor pressure; and 3) changes in cell density caused by the temporal cycling of the synthesis and degradation of carbohydrate reserves (van Liere and Walsby, 1982; Walsby, 1978, 1987). Gliding motility coupled with phototaxis permits many filamentous cyanobacteria to move to areas of optimal light conditions (Castenholz, 1982). In microbial mats, for example, filamentous cyanobacteria can migrate to different levels within the mat in response to light intensity.

Cyanobacteria are predominantly photoautotrophic although some are capable of heterotrophy when grown under laboratory conditions. The ability to grow photoheterotrophically using simple organic compounds as sole carbon sources and light as a source of energy is relatively common among cultured cyanobacteria, whereas the ability to grow chemoheterotrophically in the dark using an organic compound as a sole source of carbon and energy is more restricted (Rippka et al., 1979). The significance of photoheterotrophy and chemoheterotrophy to cyanobacteria in natural environments is still unresolved (Smith, 1982). However, it is unlikely that either process will be found to be important to the metabolism of free-living cyanobacteria, since the range of substrates is limited to a restricted number of simple sugars that can be metabolized via the oxidative pentose-phosphate cycle, and the concentrations of these compounds are usually too low in nature to contribute significantly to cyanobacterial carbon metabolism.

Cyanobacteria are also capable of mixotrophy, a process in which a variety of organic compounds, such as amino acids, that cannot serve as sole carbon sources, are assimilated as a supplement to autotrophic CO_2 fixation. This use of organic compounds is potentially more important than either photo- or chemoheterotrophy to the metabolism of free-living cyanobacteria in nature, but it is poorly documented at present.

The ability of many cyanobacteria to fix dinitrogen permits them to exploit habitats low in combined nitrogen. One of the key physiological properties of nitrogenase, the enzyme system responsible for dinitrogen fixation, is its sensitivity to oxygen inactivation and repression. This presents an acute problem for nitrogen-fixing cyanobacteria that not only live in oxygenated environments but also produce oxygen during photosynthesis. Some filamentous cyanobacteria have solved this problem by spatially separating the processes of oxygenic photosynthesis and dinitrogen fixation through the production of highly differentiated cells, known as heterocysts, that are specialized sites of dinitrogen fixation (Bothe, 1982). Heterocysts lack the ability to carry out oxygenic photosynthesis. There are also a growing number of nonheterocystous, filamentous (Pearson et al., 1979; Stahl and Krumbein, 1985) and unicellular (Gallon et al., 1974; Huang and Chow, 1986, 1988; Mitsui et al., 1987) cyanobacteria that are capable of fixing dinitrogen by temporally separating these processes. In these organisms, photosynthesis occurs during the light period, while dinitrogen fixation occurs during the dark at the expense of carbohydrate reserves (glycogen) built up during the photosynthetic period.

Cyanobacteria are found in environments with quite different temperature ranges. Most cyanobacteria are mesophilic and live in environments where temperature may range from freezing to 40°C. They typically have growth optima between 20 and 35°C and maximum tempera-

tures permitting growth below 45°C. Cyanobacteria isolated from the open oceans, where temperature ranges are more moderate, often have temperature maxima near 30°C (Waterbury et al., 1986). One tropical, marine, unicellular, nitrogen-fixing cyanobacterium has a temperature range permitting growth only between 26°C and 32°C, which is one of the narrowest temperature ranges known for a free-living mesophilic prokaryote.

Cyanobacteria are also commonly found in more extreme environments. In Antarctica, they are present as cryptoendoliths in rocks in the cold dry deserts and in the plankton and microbial mats of lakes. With the exception of one strain of *Chroococcidiopsis* sp. that is a psychrophile, the cyanobacterial isolates from the Antarctic desert rocks are mesophiles, with temperature optima near 35°C (I. Friedmann, personal communication). On the other hand, many of the cyanobacteria isolated from Antarctic lakes are psychrophiles, having maximum temperatures permitting growth of 20°C (Seaburg, 1981).

Cyanobacteria, including representatives of each of the five orders, are conspicuous inhabitants of hot springs where they occur at temperatures up to 74°C. Thermophilic strains of cyanobacteria have growth optima above 45°C and often fail to grow, but can survive at room temperature (Castenholz, 1981).

Cyanobacteria occur in habitats of widely differing salinity. Freshwater habitats contain diverse and often prominent populations of cyanobacteria. In marine habitats, cyanobacterial isolates can be divided into two categories based on their major ionic requirements for growth. Some are halotolerant and grow equally well on a medium with either a seawater or freshwater base. Others have obligate requirements for concentrations of sodium, magnesium, calcium, and chloride that reflect the chemistry of seawater. These requirements are not met by supplementing freshwater media with sodium chloride alone (Waterbury et al., 1986). Many cyanobacteria isolated from soils are tolerant of salt concentrations in excess of 1 M NaCl, whereas marine isolates usually fail to grow at this concentration, probably because the salinity of seawater has been relatively constant for long periods.

The occurrence of cyanobacteria in hypersaline environments is well documented in the classical descriptive literature (Hof and Frémy, 1933) but only a very restricted group is truly halophilic. Individual strains of *Aphanothece halophytica* isolated from a salt evaporation pond (Yopp et al., 1978), from Great Salt Lake, Utah (Brock, 1976), and the Solar Lake, Sinai, Israel (Cohen, 1975) each have major ionic requirements for growth that reflect the chemistry of their individual habitats. The isolates from the salt evaporation pond and from Great Salt Lake are truly halophilic. They grow optimally in approximately 2 M NaCl and have minimum NaCl requirements for growth of 0.7 M and 1.0 M NaCl, respectively.

Cyanobacteria are most prominent in habitats with neutral to alkaline pH. They are excluded from highly acidic environments but are characteristic inhabitants of acidic hot springs and peat bogs where the pH is above 5 (Castenholz, 1981, 1988b). To date, isolates from acidic hot springs and peat bogs grow optimally at neutral pH, indicating that they are mildly acid-tolerant rather than acidophilic (Rippka et al., 1981a). A restricted number of cyanobacteria are characteristic of highly alkaline habitats; for example, *Spirulina platensis*, a dominant cyanobacterium in highly alkaline lakes, has a pH optima for growth between 8 and 11 (Ciferri, 1982).

Cyanobacteria are often found under conditions of extreme desiccation in habitats ranging from soils to both tropical and Antarctic deserts (Fogg et al., 1973). Viability can be maintained for extended periods under desiccated conditions but active growth is limited to wet seasons (de Winder et al., 1989).

Although cyanobacteria are present, and in many instances, conspicuous, under extreme conditions of temperature, salinity, pH, and desiccation, cultures isolated from these habitats often possess optima for growth that are more moderate. Thus, many cyanobacteria seem to be able to tolerate extreme environments but relatively few are obligate extremophiles.

In addition to the diverse habitats occupied by free-living forms, cyanobacteria also occur in symbiosis with a wide variety of eukaryotes (see Cyanobacterial-Plant Symbioses in Volume 1). The ability of cyanobacteria to fix dinitrogen usually plays an important role in these associations.

Isolation and Purification

There have been numerous reviews detailing procedures for the isolation and purification of cyanobacteria. General treatments include Castenholz (1988a), Castenholz and Waterbury (1989), and Rippka (1988a). Articles concerning specific groups of cyanobacteria include Castenholz (1988b) for thermophiles, Wolk (1988) for filamentous nitrogen fixers, and Mitsui and Cao (1988), Waterbury et al. 1986, and Waterbury and Willey (1988) for marine cyanobacteria. In addition, the chapters on cyanobacteria included in this Volume (Starr et al., 1981) contain methods and media that are still timely. The discussion here is a synopsis of the literature cited above.

Collection and Treatment of Samples

Many cyanobacteria are conspicuous in nature, a feature that greatly facilitates sample collection. They are conspicuous as major components of microbial mats in both freshwater and marine marshes, in desert microbial crusts, on moist rocks in terrestrial habitats, and in the marine intertidal zone and as epiphytic colonies on terrestrial and freshwater plants and marine macroalgae. They are often less conspicuous in aquatic environments but characteristic species of planktonic cyanobacteria form dense blooms in both freshwater and marine environments (Walsby, 1981). Even in aquatic environments where blooms are not evident, small unicellular cyanobacteria are often abundant and important components of the microbial food webs in freshwater lakes (Caron et al., 1985; Pick and Caron, 1987) and in the open ocean (Waterbury et al., 1986).

The first step in isolating cyanobacteria should be a careful description of the sampling site. In addition to the site location and description, parameters such as light intensity, temperature, pH, and salinity, should be recorded. This information is not only useful for describing the natural habitat of the cyanobacteria to be isolated but can be critically important when designing culture media and conditions of incubation.

Samples for enrichment of cyanobacteria that are not growing submerged in water can be sampled by removing rock chips, microbial tufts, etc., and placing them in small containers. The collected samples should not be immersed in water but should be kept moist by the addition of wetted paper to avoid growth of contaminating microorganisms. Precaution should be taken to avoid contamination in collecting and storing water samples from which cyanobacteria are to be cultured. In extreme cases, for example, to isolate cyanobacteria from very oligotrophic waters, it is necessary to rigorously clean water samplers, storage containers, and culture vessels with acid followed by repeated washings with ultrapure deionized water. Samples of natural populations should be transported to the laboratory for processing as quickly as possible, taking care to avoid exposing them to extremes of temperature or light.

Prior to culturing, samples should be examined carefully and if possible photographed using light microscopy to determine and document the identity and relative abundance of the cyanobacteria present and to assess the extent of contamination by undesirable microorganisms. The identification of cyanobacteria in field samples is best achieved using the botanical descriptive literature. The treatise of Geitler (1932) or later treatises that follow the "Geitlerian School" have proven to be the most useful (Anagnostidis and Komárek, 1985, 1988; Bourrelly, 1985; Desikachary, 1959; Komárek and Anagnostidis, 1986).

Portions of nonaqueous natural samples in which the cyanobacteria are conspicuous should be preserved (usually by drying) and deposited in a recognized herbarium to satisfy the botanical requirement for type material. In practice, good photomicrographs of the natural material will provide excellent supplementary documentation of the type material and will aid in correlating the identity of the cyanobacteria in the natural material with the identity of cultures isolated from the sample.

Except in rare instances where the natural sample appears to be monospecific, it will be necessary to physically manipulate the sample both to break up compact clumps of organisms and to separate the cyanobacterium of particular interest from other cyanobacteria and contaminating microorganisms. A good method of dispersal in samples that contain unicellular forms is to gently grind the natural material, wetted with sterile medium, between two sterile microscope slides. Samples containing filamentous forms can be dispersed using sterile dissecting needles to tease apart clumps or tufts of natural material that have been placed in drops of sterile medium in the bottom of petri dishes. This process is facilitated by monitoring and making the manipulations using a dissecting microscope.

Once the samples have been dispersed it is often possible to remove some of the contaminating bacteria by washing with sterile medium. This can be accomplished for samples containing unicellular cyanobacteria by repeatedly washing the cells in a small sterile filter apparatus set up with a membrane filter with a pore size slightly smaller than the cyanobacterial cell. With the aid of a dissecting microscope, samples containing filamentous cyanobacteria can often be washed by picking individual trichomes with a platinum needle or a drawn-out Pasteur pipette. The individual trichomes are then passed through successive large drops of sterile liquid medium in the bottom of a petri dish or they can be dragged through solidified agar medium to physically remove attached contaminating organisms.

Media and Growth Conditions

Many media have been described for cyanobacteria. Included here are nine different media, some of which have proven successful for the isolation and maintenance of a wide variety of cyanobacteria and some designed for the growth of more specialized groups (Tables 1 and 2).

Since they are photoautotrophs, cyanobacteria can be grown in simple mineral media. Vitamin B_{12} is the only growth factor known and is only

[h]The disodium EDTA should be added first.

required by a few marine isolates (Waterbury and Stanier, 1978). Media should be designed to mimic the chemical composition of the environment from which cyanobacteria are to be isolated. In addition, they must be supplemented with essential nutrients needed to support cell growth, including sources of nitrogen, phosphorus, trace elements, etc. When cyanobacteria are being isolated from extreme environments, it is prudent to use two different media: one having the characteristics of the extreme environment and one in which the extreme variable(s) is moderated. Nutrient levels in growth and maintenance media are usually high to support large cell yields. It is often advantageous to dramatically lower the nutrient levels in media that are used for enrichment and isolation. For example, compare the high nutrient levels in medium BG-11 with those in Aquil (Table 1).

To date, several hundred cyanobacteria, including representatives from most of the major groups, have been isolated and purified using standard microbiological techniques. Despite this success there still are many cyanobacteria that have not yet been cultured. Of these, cyanobacteria characteristically found in the oligotrophic waters of the oceans and freshwater lakes have been particularly problematic.

It is likely that our inability to culture certain cyanobacteria is not because we fail to add something to the medium that the organisms require, but rather because we inadvertently add constituents that are toxic. Toxicity may derive from contaminants left on the surface of inadequately cleaned samplers and culture vessels, from contaminants present in either the chemicals or water used to make culture media, or from the intentional addition of necessary compounds to culture media in quantities high enough to become toxic.

The addition of copper to cyanobacterial media is an interesting example. Copper is a nearly universal component of trace element solutions used to supplement culture media for a wide variety of microorganisms, including cyanobacteria (Table 2). However, copper has

also been shown to be extremely toxic. Rueter et al. (1979) examined the effects of copper on *Trichodesmium thiebautii*, a prominent and, at that time, unculturable oceanic cyanobacterium. They found that the addition of 10^{-8} M copper caused a marked decrease in the rate of CO_2 fixation by natural populations of *T. thiebautii*. Waterbury and Stanier (1978) used a marine medium (MN) to isolate and culture a wide variety of intertidal marine cyanobacteria. Medium MN had a natural seawater base and used nutrient additions and trace metals from medium BG-11 (Tables 1 and 2). It proved quite successful for the isolation of coastal marine cyanobacteria but would not support the growth of open-ocean strains of marine *Synechococcus* spp. (Waterbury et al., 1979, 1986). The fact that medium MN contained 3.2×10^{-7} M copper, more than was necessary to inhibit photosynthesis in *Trichodesmium* sp., led us to design medium SN, whose principal difference from medium MN was the omission of copper from its trace metal solution (Table 2). Medium SN and its more dilute form, SNAX, have been used successfully for the maintenance and isolation of many oceanic and coastal marine cyanobacteria.

Ohki et al. (1986) succeeded in culturing *Trichodesmium thiebautii* and *T. erythraeum* using the artificial seawater medium Aquil (Morel et al., 1979; see also Table 1) in which the phosphate was reduced to 0.5 µg/l and copper was deleted from the trace element solution (PIV) (Table 2). Aquil was designed to minimize heavy metal contamination by passing its major nutrients through Chelex 100 columns (Bio-Rad Laboratories, Richmond, CA). Two factors seem to have contributed to the successful culturing of *Trichodesmium* spp.: the removal of heavy metals from the nutrients added to Aquil and the omission of copper as a trace element.

Copper may also have played a role in the culturing of freshwater planktonic cyanobacteria. Medium Z8, originally described by Kotai (1972), has been used by Skulberg and his colleagues (Skulberg, 1983) to isolate and maintain a large collection of freshwater planktonic cyanobacteria. Skulberg used Gaffron's trace element solution as described by Hughes et al. (1958). In the paper by Hughes et al. (1958), Gaffron's trace element solution did not contain copper, but by 1960 (Zehnder and Gorham, 1960) copper had been added to Gaffron's trace metal solution.

These examples suggest that it may be beneficial to omit copper from all trace element solutions used to grow cyanobacteria. If cyanobacteria have a copper requirement for growth, it can probably be met by traces present as contaminants in the water and the chemicals used to make the medium.

The quality of water and the purity of chemicals used to make media are critically important

for the successful cultivation of cyanobacteria. Freshwater media and nutrient stock solutions should be made with either double-distilled water or, preferably, with single-distilled water which has been subject to ion exchange and to activated charcoal columns such as the Millipore-Q water purifier. Marine cyanobacteria usually do best in media made with natural seawater. Seawater should be filtered through glass fiber filters at the time of collection and may be stored for extended periods prior to use in carefully cleaned plastic carboys. Chemicals used to prepare both basal media and nutrient solutions should be of the highest quality. In situations where heavy metal contamination is critical, for example, in culturing oligotrophic cyanobacteria such as *Trichodesmium* spp., both the basal medium and nutrient solutions can be treated with Chelex 100 (Morel et al., 1979).

Care should also be taken to assure that glass and plastic ware that are used to culture cyanobacteria are carefully cleaned. In situations where cleanliness is critical, for example, to avoid trace metal contamination, the following protocol that is a modification of one proposed by Fitzwater et al. (1982) can be used. Glass or plastic ware are soaked in Micro detergent (International Products Corporation, Trenton, NJ 08602-0118) at a final concentration of the detergent of 20 ml per l of Super-Q water (Millipore) for one week with occasional agitation. The vessels are then rinsed eight times in Super-Q water and then soaked in high-quality 0.5 N HCl for an additional week, followed by eight washes in Super-Q water.

Liquid Media

Medium BG-11 (Table 1), originally described by Hughes et al. (1958) and modified by Allen (1968), has been widely used for the isolation and maintenance of many cyanobacteria. When it is used as an enrichment medium it is beneficial to reduce the nitrate concentration by as much as a factor of 10 (Rippka, 1988a). A variant of this medium called BG-11_0 lacks sodium nitrate and is used for cyanobacteria capable of dinitrogen fixation. Sodium lost by the removal of sodium nitrate should be replaced by the addition of 1.0 g/liter NaCl to medium BG-11_0.

Medium Z8, originally described by Kotai (1972), has been used by Skulberg (1983) to isolate and maintain a large collection of freshwater planktonic cyanobacteria. The omission of copper from its trace element solution may be the key to its ability to support the growth of freshwater oligotrophic cyanobacteria.

Medium D was developed by Castenholz (1981) to isolate and maintain thermophilic cyanobacteria. Variants of this medium (Casten-

holz, 1988a) have also been used to culture a wide variety of nonthermophilic cyanobacteria.

Medium AO is a very alkaline medium used by Aiba and Ogawa (1977) for the isolation and maintenance of *Arthrospira platensis,* a filamentous cyanobacterium characteristic of alkaline lakes.

Aquil is a defined marine medium designed by Morel et al. (1979) for trace metal studies with marine phytoplankton. Ohki et al. 1986 used Aquil modified by a threefold reduction in the phosphate concentration to successfully culture *Trichodesmium* spp., an important oceanic dinitrogen-fixing cyanobacterium that had hitherto been unculturable. Detailed instructions for the preparation of Aquil are given in Morel et al. (1979).

Medium SN and its more dilute counterpart SNAX are marine media that have been used to maintain and isolate a wide variety of open-ocean unicellular cyanobacteria (Waterbury et al., 1986; Waterbury and Willey, 1988). They have replaced medium MN (Waterbury and Stanier, 1978, 1981), which had been used to culture coastal isolates but failed to support growth of the open-ocean cyanobacteria. The principal difference between them is that medium SN contains no added copper in the Cyano trace element solution (Table 2).

Medium RC is a medium used by van Rijn and Cohen (1983) to support the growth of a halotolerant strain of *Aphanothece halophytica* isolated from Solar Lake, Sinai, Israel. This strain grew optimally at salinities between 0.5 and 1 M NaCl but could tolerate salinities approaching 3 M NaCl.

The YOPP medium was designed to support the growth of an obligately halophilic strain of *Aphanothece halophytica* that was isolated from a salt evaporation pond in the southern San Franciso Bay (Yopp et al., 1978). Their strain grew optimally in approximately 2 M NaCl and had a minimum NaCl requirement for growth of 0.7 M.

Solid Media

Solid media should be prepared by separate autoclaving of the agar and mineral solutions, and subsequent mixing after they have cooled to 50°C (Allen, 1968). The agar concentration should be kept as low as possible, maintaining just enough firmness to permit streaking. Growth of cyanobacteria is often slow, requiring long incubation times. To prevent the agar plates from drying they should contain approximately 40 ml of medium per petri dish and should be incubated in clear plastic boxes (available in stores as vegetable crispers or sweater boxes).

The general protocol described has been modified as follows for more fastidious marine unicellular cyanobacteria (Waterbury et al., 1986; Waterbury and Willey, 1988): Solid media are prepared using Difco Bacto-agar that has been further purified as follows: 100 g of agar is washed by stirring with 3 liters of double-distilled water in a 4-liter beaker. After 30 min of stirring, the agar is allowed to settle, the wash water is siphoned off, and the agar is filtered onto Whatman F4 filter paper in a Büchner funnel. This procedure is repeated once more or until the filtrate is clear. The agar is then washed with 3 liters of 95% ethanol followed by a final 3-liter wash with analytical grade acetone. The agar is then dried at 50°C in glass baking dishes for 2–3 days and stored in a tightly covered container. Solid media prepared with the purified agar at a final concentration of 0.7% are sufficiently stable for streaking.

To prepare 40 agar plates of medium SN from 1 liter of medium, the following three solutions are prepared and autoclaved separately: 1) 750 ml of filtered seawater in a Teflon bottle; 2) 7.0 g super-clean agar in 200 ml of double-distilled water in a 2-liter glass flask; and 3) the mineral salts for 1 liter of medium in 50 ml of double-distilled water in a 125-ml glass flask. After autoclaving, the seawater and minerals are added to the flask of agar. Sterile sodium sulfite (2 mM final concentration) is added aseptically to the hot agar solution, which is then cooled to 50° before the plates are poured. It is critical that the surface of agar plates be dry prior to streaking.

Conditions of Incubation

Light Although cyanobacteria occur naturally under a wide range of light conditions, they usually grow best when cultured at light intensities varying from 10–75 $\mu Ein \cdot m^{-2} \cdot sec^{-1}$ supplied by warm- or cool-white fluorescent lamps. Traditionally, cyanobacteria have been cultured under conditions of constant illumination; however, some cyanobacteria, for example, nonheterocystous nitrogen fixers that temporally separate dinitrogen fixation and photosynthesis, require a light-dark cycle. We recommend that during isolation and purification, cultures be incubated in a light-dark cycle with a 14-h light period and a 10-h dark period.

Temperature The temperature of incubation during isolation and purification should be chosen on the basis of the temperature range of the natural environment where the sample was taken. During the initial stages of isolation it is prudent to incubate samples at several temperatures until the range that will support good growth is determined.

Techniques of Isolation and Purification

Isolation and purification are facilitated by the fact that cyanobacteria are prominent and visible components of many habitats. Natural samples can be collected, dispersed, and the individual cyanobacteria isolated directly. Samples in which unicellular forms predominate can be streaked on agar plates. Samples rich in gliding filamentous forms can be teased apart and small portions of inoculum placed in the center of agar plates. Whole trichomes or hormogonia will glide away from the central inoculum, and these migrating trichomes can be removed with a platinum spade by cutting out a small block of agar and transferring it to a new agar plate. In addition to the direct isolations on agar plates, secondary cultures for each sample should be established in the appropriate liquid medium. Aqueous samples that are too dilute to isolate colonies directly on agar plates should be enriched in a liquid medium. Serial dilution of aqueous samples during the enrichment process often aids in isolating cyanobacteria.

Although successive streaking or transferring from agar plate to agar plate is the standard method for purifying cyanobacteria, there are innumerable variations that can be tried, many of which are described in the reviews cited at the beginning of the section on isolation and purification.

Purification of unicellular cyanobacteria can be achieved by streaking on solid media. It is usually advisable to transfer isolated colonies picked from agar plates into liquid medium and to allow them to grow up before restreaking. Motile filamentous cyanobacteria can be purified by transferring individual trichomes or hormogonia to new agar plates and allowing them to glide away from the contaminants before transferring them to a successive plate.

Small heterotrophic bacteria are frequently nearly invisible contaminants of cyanobacterial cultures, and success at purifying cyanobacteria requires diligence. Agar plates should be examined daily with a dissecting microscope. The time-window within which it is possible to detect isolated cyanobacterial colonies and transfer them before they become overrun by heterotrophic bacterial contaminants can be quite short. Some of the rapidly gliding filamentous forms can clean themselves of contaminants within hours of inoculation.

Careful microscopic examination of stationary phase cultures, using a combination of phase contrast and epifluorescence illumination, is the most rigorous test of purity.

Maintenance of Pure Cultures

Stock Cultures

The majority of cyanobacteria currently in pure culture are best maintained on agar slants. However, some of the planktonic cyanobacteria, especially the heavily gas-vacuolated forms, and rapidly gliding filamentous forms should be maintained in liquid cultures. Nitrogen fixers should be maintained on media devoid of combined nitrogen.

The intervals between successive transfers of stock cultures are variable. Some of the more sensitive strains must be transferred every two weeks, while others on slants may last months. Stock cultures should be incubated in low light at a temperature appropriate for the individual strains. Stock cultures of cyanobacteria should never be stored in a dark refrigerator!

Long-Term Preservation

Storage in liquid nitrogen is the best method for the long-term preservation of cyanobacteria. Dimethylsulfoxide (5–10% v/v) is added as a cryoprotectant to stationary phase cultures that have been concentrated by centrifugation. The cell concentrate is dispensed into plastic cryogenic ampules and frozen slowly at $1°C/min$ until they reach $-80°C$. The slow freezing is satisfactorily accomplished by placing the ampules in a $-80°C$ freezer for one hour. The ampules are then placed in either the vapor or liquid phase of the liquid nitrogen storage container. Samples are reactivated by placing them in a $37°C$ water bath and transferring them into fresh liquid medium immediately upon thawing. Heavily gas-vacuolated cyanobacteria can be successfully frozen in liquid nitrogen if their gas vacuoles are collapsed by centrifugation prior to freezing (Rippka et al., 1981a).

The Identification of Cyanobacteria in Pure Culture

The keys and descriptions of cyanobacteria in pure culture used here are based on the treatises of Rippka et al. (1979, 1981b) and Rippka (1988b), and on the first treatment of the cyanobacteria in *Bergey's Manual of Systematic Bacteriology* (Castenholz, 1989a, 1989b, 1989c; Waterbury, 1989; Waterbury and Rippka, 1989). The descriptions of many of the genera and "groups" are provisional. Even though several hundred different cyanobacteria have been obtained in pure culture and partially characterized, there remains an enormous amount of work before a satisfactory system of classification for

this important group of photosynthetic prokaryotes is achieved. The following key may be useful, however.

Key to the Orders of Cyanobacteria

A. Unicellular or nonfilamentous aggregates of cells held together by extracellular slime or sheath layers .... B
A. Filamentous: Range of morphology from simple trichomes to highly differentiated branching C
B. Reproduction by binary fission in one, two, or three planes, or by budding...................... Order Chroococcales
B. Cell division by multiple fission or by a combination of multiple fission and binary fission ....
.... Order Pleurocapsales
C. Cell division by binary fission in one plane at right angles to filament axis. Cell differentiation absent (terminal cells may be differentiated). Reproduction by trichome fragmentation or undifferentiated hormogonia
.... Order Oscillatoriales
C. Cell division by binary fission in one or more planes. Differentiation occurs resulting in specialized cells and structures .... D
D. Cell division in one plane at right angles to trichome axis... Order Nostocales
D. Cell division in one or more planes resulting in complex... Order Stigonematales

Comments on Genera and Groups of the Order Chroococcales

The order Chroococcales contains all the unicellular cyanobacteria, including those that divide by binary fission (family Chroococcaceae) and by budding (family Chamaesiphonaceae) (Fig. 3). Several of the genera shown in Fig. 3 are provisional and are more properly called "groups" (see below). The presence or absence and characteristics of cell aggregates and the number and regularity of the planes of division are the major characteristics used to delineate genera and groups of unicellular cyanobacteria in culture and to describe genera in the traditional botanical literature, as shown in the key below.

Key to the Genera and Groups of the Order Chroococcales*

A. Reproduction by binary fission .... B
A. Reproduction by repeated budding from the apical pole of the cell; cells ovoid; thylakoids present................
.... Genus *Chamaesiphon*
B. Thylakoids present.. C
B. Thylakoids absent; division in one plane; cells rod-shaped; sheath present........................ Genus *Gloeobacter*
C. Division in one plane .... D
C. Division in two or three planes .... F
D. Cell diameter of >3 μm; capable of aerobic N$_2$ fixation or nitrogenase produced anaerobically .... E
D. Cell diameter of <3 μm.............. *Synechococcus* group
E. Cells rod-shaped; sheath present.....................................
.... Genus *Gloeothece*
E. Cells rod-shaped; sheath absent ..... *Cyanothece* group
F. Cells coccoid to hemispherical, held together in aggregates by multilaminated sheath material..................
.... *Gloeocapsa* group
F. Cells coccoid, occurring singly, in pairs, or in aggregates held together by amorphous capsular material................
.... *Synechocystis* group

*Adapted from Waterbury and Rippka (1989).
Fig. 3. Schematic presentation of the genera assigned to the order Chroococcales. The thin lines surrounding cells designate sheath material; the presence of thylakoids is indicated by the symbol //.

Cell aggregates in the Chroococcales are held together by multilaminated sheath material or by amorphous slime or capsular material (Fig. 3). The possession of extracellular sheath layers has proven to be a stable feature of many cyanobacterial groups in culture and is a primary character used in the description of several unicellular taxa including: *Gloeobacter*, *Gloeothece*, and the *Gloeocapsa* group. Other unicellular cyanobacteria, primarily some members of the *Synechocystis* group, occur in cell aggregates in nature (and, more rarely, in culture) that are held together by amorphous slime or capsular material. Slime production has proven to be an unreliable taxonomic character because its production in culture is affected by the growth phase of the cyanobacteria and the conditions under which they were grown.

In the Chroococcales, transverse binary fission occurs in one, two, or three successive planes at right angles to one another or in irregular planes. The number and regularity of the successive planes of division are stable features of individual cyanobacteria that should in principle be readily determinable from cultured material. However, in practice, it is often difficult to determine the number of successive planes of division, with the distinction between division in two or three planes being especially problematical. As a consequence, the planes of division have not been determined for many of the strains currently in pure culture, with the result that some of the loosely defined groups, particularly the *Synechocystis* group, contain some strains that divide in two successive planes and some that divide in three successive planes.

The generic description of *Gloeothece* conforms to traditional botanical usage. Members of this genus are rod-shaped cyanobacteria that divide by transverse binary fission in a single plane. The cells occur in aggregates held together by well-defined sheath layers. The cells contain intracellular photosynthetic thylakoids, a feature that distinguishes them from *Gloeobacter*. All the strains currently placed in this genus are capable of dinitrogen fixation. *Chamaesiphon* contains unicellular cyanobacteria that divide by budding (Fig. 3). This definition conforms to botanical usage except for a difference in terminology. In the botanical literature, the smaller daughter cell (bud) resulting from unequal binary fission is termed an "exospore." *Gloeobacter* is a new genus that is not described in the botanical literature and is distinguished from other cyanobacteria by the lack of intracellular photosynthetic thylakoids (Rippka et al., 1974).

The four groups included in the Chroococcales by Waterbury and Rippka (1989) reflect the provisional nature of the taxonomy of cyanobacteria based on pure cultures. The groups are divided into "clusters," each equivalent to but not given the formal status of a genus.

The *Synechococcus* group contains coccoid to rod-shaped cyanobacteria with cells smaller than 3 μm in diameter that divide by binary fission in a single plane and that lack structured sheaths. Morphologically, all members of this group appear deceptively similar. The true extent of heterogeneity within the group is apparent from the span of the GC contents of their DNAs, which range from 39–71 mol%. Waterbury and Rippka (1989) divided the *Synechococcus* group into six clusters, three marine and three freshwater. Further subdivision and arrangement of these clusters will occur before genus designations are proposed and formalized. For example, in a phylogenetic study of the cyanobacteria, Giovannoni et al. (1988) showed that two strains included in the *Synechococcus* cluster, PCC 6301 (*"Anacystis nidulans"*), a freshwater clone, and Y7C-S (*"Synechococcus lividus"*), a thermophilic clone, are on independent deep branches in the cyanobacterial phylogenetic tree (Fig. 1). The phylogenetic distance between these two strains indicates that they should be assigned to two genera.

The *Cyanothece* group contains coccoid to rod-shaped cyanobacteria with cells larger than 3 μm in diameter that divide by binary fission in one plane and that lack sheaths. This group is superficially distinguished from the *Synechococcus* group by cell size and from *Gloeothece* and *Gloeobacter* by the absence of well-defined sheath layers. Many of the strains assigned to this group by Waterbury and Rippka (1989) are either capable of dinitrogen fixation or synthesize nitrogenase under anaerobic conditions. The heterogeneity of the group is evidenced by the fact that it currently contains freshwater, marine, and halophilic isolates.

The *Gloeocapsa* group contains cyanobacteria that divide by binary fission in two or three planes at right angles to one another, resulting in cell aggregates held together by multilaminated sheath material. In the traditional botanical literature, members of this group would be placed in either *Gloeocapsa* or *Chroococcus*.

The *Synechocystis* group contains unicellular cyanobacteria that divide by binary fission in two or three planes at right angles to one another. The cells typically occur singly or in pairs in culture, but in nature and, rarely, in culture, some can also occur in aggregates held together by amorphous capsular material. Waterbury and Rippka (1989) provisionally subdivided the group into four clusters, one containing marine isolates and three containing freshwater isolates.

Some representatives of the Chroococcales are illustrated in The Phototrophic Prokaryotes in the second edition, Figs. 8 and 10.

Comments on Genera and Groups of the Order Pleurocapsales

The order Pleurocapsales contains cyanobacteria that reproduce by the formation of small spherical cells (called baeocytes) produced through multiple fission. The unicellular genera of the order divide exclusively by multiple fission. In other genera, cell aggregates are produced by binary fission, after which some or all of the cells in the aggregates undergo multiple fission and release baeocytes (Fig. 4). The small vegetative cells that are the products of multiple fission, termed "endospores" in the botanical literature, were renamed baeocytes (Greek for small cells) by Waterbury and Stanier (1978) to avoid confusion with the bacterial endospore. The ordinal and generic definitions used here and in *Bergey's Manual of Systematic Bacteriology* (Waterbury, 1989) are those proposed by Waterbury and Stanier (1978). Some of the botanical generic definitions were modified to incorporate new properties and the reinterpretation of features from the botanical descriptive literature that were documented during the study of developmental cycles in culture.

Key to the Genera and Groups of the Order Pleurocapsales*

A. Cell division solely by multiple fission .... B
A. Cell division by a combination of binary and multiple fission C
B. Baeocytes motile .... Genus *Dermocarpa*
B. Baeocytes nonmotile .... Genus *Xenococcus*
C. Baeocyte development leads to the formation of a vegetative cell that undergoes one to three binary fissions, producing a single apical cell which divides by multiple fission and releases baeocytes; the basal cell subsequently enlarges and repeats the cycle ...... Genus *Dermocarpella*
C. Baeocyte development, followed by repeated binary fission, to produce cell aggregates of varying size and complexity .... D
D. Binary fission occurs in three planes at right angles to one another, producing a cubical aggregate of cells, all of which normally undergo multiple fission .... E
Fig. 4. Schematic presentation of genera assigned to the order Pleurocapsales. Baeocytes that are not surrounded by a fibrous (F) layer at the time of release and are, consequently, motile are symbolized by dotted circles to distinguish them from baeocytes that are surrounded by an F layer (solid circles). *Dermocarpa:* A, symmetric baeocyte enlargement; B, multiple fission, leading to baeocyte formation; C, baeocyte release followed by a brief period of baeocyte motility. *Xenococcus:* A, symmetric baeocyte enlargement; B, multiple fission leading to baeocyte formation; C, release of immotile baeocytes. *Dermocarpella:* A, asymmetric baeocyte enlargement; B, binary fission, giving rise to a small basal cell and a larger apical cell; C, multiple fission of the apical cell, leading to baeocyte formation; D, baeocyte release; E, period of baeocyte motility; F, enlargement of basal cell. *Myxosarcina:* A, symmetric baeocyte enlargement to a predetermined size; B, repeated binary fission in three regular planes; C, multiple fission of almost all the cells in the aggregate, followed by baeocyte release; D, period of baeocyte motility. *Chroococcidiopsis:* A, symmetric baeocyte enlargement to a predetermined size; B, repeated binary fissions in three regular planes; C, multiple fission of almost all the cells in the aggregate, followed by the release of immotile baeocytes. *Pleurocapsa* subgroup I: A, symmetric baeocyte enlargement; B, binary fissions in many irregular planes; C, multiple fission of some vegetative cells; D, baeocyte release; E, period of baeocyte motility. *Pleurocapsa* subgroup II: A, asymmetric baeocyte enlargement; B, binary fission in many irregular planes; C, multiple fission of some vegetative cells; D, baeocyte release; E, period of baeocyte motility. (From Waterbury and Stanier, 1978.)

D. Binary fission occurs in many different planes, to produce irregular, sometimes pseudo-filamentous aggregates of cells. Some or all of the cells in the aggregate undergo multiple fission ....*Pleurocapsa* group
E. Baeocytes motile .... Genus *Myxosarcina*
E. Baeocytes nonmotile.......... Genus *Chroococcidiopsis*

*Adapted from Waterbury (1989).

The genera *Dermocarpa* and *Xenococcus* are unicellular cyanobacteria that divide solely by multiple fission (Fig. 4). Their developmental patterns are similar, differing only with respect to baeocyte motility. The baeocytes of *Dermocarpa* are capable of gliding motility for a short period following their release from the parental cell, whereas in *Xenococcus*, the baeocytes are nonmotile. *Dermocarpella* represents the simplest pleurocapsalean cyanobacterium, whose developmental cycle incorporates division by both binary and multiple fissions. The baeocyte enlarges asymmetrically into an ovoid vegetative cell, which then undergoes binary fission to form a large apical cell and from one to three smaller basal cells. The large apical cell then undergoes multiple fission and releases motile baeocytes. Subsequently the basal cells enlarge and undergo binary fission and repeat the cycle. The developmental patterns of *Myxosarcina* and *Chroococcidiopsis* are very similar, differing only with respect to baeocyte motility (Fig. 4). The baeocyte enlarges symmetrically into a vegetative cell of fixed strain-specific size. The vegetative cell then begins to divide by binary fission in three alternating planes at right angles to one another to produce a large, approximately cubical, cell aggregate. Multiple fission, when it occurs, is massive; almost all the cells in the aggregate undergo cleavage and release baeocytes.

The *Pleurocapsa* group includes a large number of internally diverse strains. Their development involves baeocyte enlargement, followed by binary fission in irregular planes to produce cell aggregates that differ widely in size and complexity in different strains (Fig. 4). They range from small, compact masses of cells to large structures, consisting of a central mass of cells from which radiate more or less extensive pseudofilamentous outgrowths. Eventually, some cells in the aggregate undergo multiple fission and produce motile baeocytes. The baeocyte enlarges symmetrically, into a spherical vegetative cell (strains of subgroup I), or asymmetrically, into an elongated vegetative cell (strains of subgroup II), before the onset of binary fission.

A representative of the genus *Dermocarpa* and a member of the Pleurocapsa group are illustrated in The Phototrophic Prokaryotes in the second edition, Figs. 11 and 12.

Comments on Genera and Groups of the Order Oscillatoriales

The order Oscillatoriales contains filamentous cyanobacteria that divide by binary fission in a single plane (Fig. 5). Trichomes are made up solely of vegetative cells; differentiation, if it occurs, is limited to morphological changes in the terminal cells of filaments.

Phycological treatments to delineate genera of this order rely heavily on the presence or absence and the characteristics of extracellular sheath material. Although sheaths are still used as a character to define oscillatorian genera in pure culture, primary emphasis is placed on the size, shape, and arrangement of the cells within filaments (Castenholz, 1989a; Rippka, 1988b).

Key to the Genera and Groups of the Order Oscillatoriales

A. Trichomes straight or loosely coiled for a portion of their length C
A. Trichomes helically coiled .... B
B. Cross-walls between vegetative cells invisible by light microscopy.................................. Genus *Spirulina*
B. Cross-walls visible between vegetative cells .... Genus *Arthrospira*
C. Cells disk-shaped (wider then long) .... D
C. Cells isodiametric or cylindrical .... E
D. Trichomes with distinct sheath .... Genus *Lyngbya*
D. Trichomes without or with very thin sheath.................. .... Genus *Oscillatoria*
E. Cells cylindrical, several trichomes harbored within a common sheath................................... Genus *Microcoleus*
E. Trichomes not within a common sheath..................... F
Fig. 5. Schematic presentation of the genera assigned to the order Oscillatoriales. The thin lines surrounding trichomes designate sheath material. LPP-group A consists of the genus *Lyngbya*. The polar bodies in *Pseudanabaena* are gas vacuoles.

F. Cells cylindrical, constriction occurs at cross-walls and gas vacuoles occur at cell poles..
.... Genus *Pseudanabaena*
F. Cells isodiametric or cylindrical, with or without sheaths, motile or nonmotile............................ LPP group

The genera *Spirulina* and *Arthrospira* are filamentous cyanobacteria with helically coiled trichomes (Fig. 5). In *Spirulina* the trichomes are tightly coiled, and the cross-walls between adjacent vegetative cells are not visible by light microscopy. The trichomes in *Arthrospira* are loosely coiled and the cross-walls are evident by light microscopy. Ultrastructural studies by Guglielmi and Cohen-Bazire (1982) demonstrated that the arrangement of pores in the peptidoglycan layer of the cell wall was different in *Spirulina* and *Arthrospira* but the arrangement in *Arthrospira* and members of the genus *Oscillatoria* was similar. In some botanical treatments (Bourrelly, 1985), *Arthrospira* is included within the genus *Oscillatoria*. Further study is needed to circumscribe these genera.

The genera *Oscillatoria* and *Lyngbya* (both sensu Rippka, 1988b) both include filamentous cyanobacteria with straight trichomes composed of disk-shaped cells (cells much wider than they are long) (Fig. 5). In *Oscillatoria*, the trichomes lack sheaths or are very lightly sheathed and exhibit gliding motility involving trichome rotation during translocation. The trichomes of *Lyngbya* are heavily sheathed and nonmotile. Undifferentiated hormogonia are released from the ends of the sheath and are motile for a period until new sheath material is synthesized. These definitions are more restrictive than those used by Castenholz (1989a), which also include forms with cells longer than they are wide.

The genus *Microcoleus* contains filamentous cyanobacteria with straight trichomes composed of cylindrical cells. Although this genus is not currently recognized by Rippka (1988b), because the common sheath is often not produced in culture, the common sheath is very characteristic in field material.

The genus *Pseudanabaena* contains filamentous cyanobacteria with unsheathed motile trichomes composed of cylindrical to barrel-shaped cells (Fig. 5). The cells usually contain polar gas vacuoles, and the cell walls are normally constricted at the junction between adjacent vegetative cells. They are capable of gliding motility but translocation is not accompanied by trichome rotation.

The LPP group (sensu Rippka, 1988b) contains a heterogeneous assemblage of filamentous cyanobacteria including forms that would be assigned to genera such as *Phormidium* and *Plectonema* in the botanical literature. LPP-

group A is actually *Lyngbya* (Fig. 5). A satisfactory resolution of this group awaits more detailed study.

Some representatives of the Oscillatoriales are illustrated in The Phototrophic Prokaryotes in the second edition, Figs. 9 and 13.

Comments on the Genera of the Orders Nostocales and Stigonematales

Members of the orders Nostocales and Stigonematales are distinguished from the filamentous cyanobacteria in the order Oscillatoriales by their capacity for cellular differentiation (Figs. 6 and 7). In the absence of combined nitrogen, some vegetative cells in or at the ends of trichomes develop into heterocysts. Mature heterocysts are distinguishable from vegetative cells by their thick cell walls, relatively weak pigmentation, and refractile polar granules at points of attachment to adjacent vegetative cells. When mature, a heterocyst can neither divide nor revert to a vegetative cell; it is the specific cellular site of nitrogen fixation under aerobic conditions (Wolk, 1982). Members of the Nostocales and the Stigonematales are truly multicellular as a result of cellular differentiation and functional specialization between vegetative cells and heterocysts.

Many members of these two orders also produce thick-walled resting cells known as akinetes. Mature akinetes are usually larger than vegetative cells, have a lower phycobiliprotein content, and may produce pigments that give them a brownish appearance. They also contain large amounts of reserve material (Herdman, 1987; Nichols and Adams, 1982). They are formed as cultures approach the stationary phase of growth and are usually not dependent on the nature of the nitrogen source, except in those cyanobacteria that only form akinetes adjacent to heterocysts (e.g., *Cylindrospermum*). In such cases, repression of heterocyst formation by combined nitrogen is coupled with the repression of akinete formation. Akinetes are resistant to desiccation and to cold, but not to heat. They germinate under favorable growth conditions and give rise to new filaments.

The number of planes of division is the sole character that separates the orders Nostocales and Stigonematales. In members of the Nostocales, cell division always occurs in a single plane at right angles to the long axis of the trichomes, which are consequently uniseriate and unbranched (Fig. 6). Members of the Stigonematales are capable of division in more than one plane, giving rise to true branches and both multiseriate and uniseriate trichomes (Fig. 7).

Fig. 6. Schematic presentation of the genera assigned to the order Nostocales. (a) Without developmental cycle; (b) with developmental cycle. Heavy-walled cells with polar granules represent heterocysts; heavy-walled cells that are stippled represent akinetes; thin lines surrounding trichomes designate sheath material.
Fig. 7. Schematic presentation of two of the genera assigned to the order Stigonematales. Heavy-walled cells with polar granules represent heterocysts; heavy-walled cells that are stippled represent akinetes; thin lines surrounding groups of cells designate sheath material.
Key to the Genera of the Order Nostocales

A. Reproduction by trichome breakage (hormogonia not produced) or by germination of akinetes (if they are produced) .... B
A. Reproduction by hormogonia that are morphologically distinguishable from vegetative trichomes; reproduction may also occur by trichome breakage and akinete germination .... D
B. Heterocysts are terminal, may occur at both ends of trichomes. Akinetes (when present) are directly adjacent to heterocysts .... Genus *Cylindrospermum*
B. Heterocysts intercalary or terminal; location of akinetes (when present) variable C
C. Vegetative cells spherical, ovoid, or cylindrical.............
.... Genus *Anabaena*
C. Vegetative cells shorter than wide to disk-shaped........
.... Genus *Nodularia*

D. Heterocysts are terminal; mature trichomes taper from base near heterocyst to tip .... Genus *Calothrix*
D. Trichomes do not taper... E
E. Trichomes heavily sheathed, false branching may occur usually at site of intercalary heterocyst. Hormogonia produce heterocysts at one end of filaments only ....
.... Genus *Scytonema*
E. Trichomes not sheathed, false branching absent. Hormogonia produce heterocysts at both ends of young filaments.. Genus *Nostoc*

Nostocalean genera currently available in pure culture can be divided into two groups by their capacity to produce hormogonia: One group, the genera *Cylindrospermum*, *Nodularia*, and *Anabaena*, do not form hormogonia (Fig. 6). Reproduction in these genera is by trichome

breakage or by the germination of akinetes if they are produced. The definitions of the genera *Cylindrospermum* and *Nodularia* correspond to traditional botanical definitions: Members of the genus *Cylindrospermum* produce untapered trichomes with a terminal heterocyst. Akinetes are always produced adjacent to heterocysts. Members of the genus *Nodularia* produce untapered trichomes composed of cells that are wider than long (disk-shaped). Heterocysts in this genus are differentiated from both terminal and intercalary cells. The distinction between the genera *Anabaena* and *Nostoc* is problematic. In the botanical literature, the distinction between the two genera is made on the basis of slime production; in the genus *Nostoc*, this results in characteristic macroscopic colonies when observed in natural material. In culture, the morphology of filaments in the two genera is similar; there, their distinction rests on the production of hormogonia by *Nostoc* and their absence in *Anabaena*, a distinction that may be difficult to make because some strains of *Nostoc* only produce hormogonia erratically (Lachance, 1981; Rippka, 1988b).

Members of the genera *Scytonema* and *Calothrix* share with *Nostoc* the ability to form differentiated hormogonia (Fig. 6). However, the pattern of development of hormogonia into mature filaments differs in each genus. The hormogonia in all three genera are initially devoid of heterocysts. In *Nostoc,* the hormogonia form two heterocysts, one at each end of the filament. Subsequent growth gives rise to mature trichomes in which intercalary heterocysts are also produced. In *Scytonema* and *Calothrix*, heterocyst formation in the developing hormogonia is restricted to the terminal position at only one end of the cellular chain.

In *Scytonema*, growth and elongation of hormogonia give rise to heavily sheathed trichomes of constant width, in which heterocysts are predominantly intercalary. In *Calothrix*, hormogonia that are composed of cells of constant width give rise to tapered trichomes. The direction of tapering that is characteristic of *Calothrix* is determined by the location of the first heterocyst produced. Members of the genus *Calothrix* (sensu Rippka, 1988b) are often included in a number of traditional genera such as *Gloeotrichia*, *Rivularia*, *Isactis*, and *Dichothrix*.

Key to the Genera of the Order Stigonematales

A1. Cells of mature trichome are spherical and divide in multiple planes. The resulting cell aggregates are irregular in shape and appear more unicellular than filamentous. Some cells undergo a series of divisions in one plane to produce short motile hormogonia..
.... Genus *Chlorogloeopsis*
A2. True branching results from lateral division along main axis of the filamcent .... *See* B.

B1. Cells of lateral branches are morphologically different from the cells in the main axis............. Genus *Fischerella*
B2. Cells of lateral branches are not morphologically different from the cells in the main axis..................... *See* C.

C1. Trichomes uniseriate throughout................................
.... Genus *Hapalosiphon*
C2. Trichomes multiseriate, at least in part......................
.... Genus *Stigonema*

The genus *Chlorogloeopsis* is a member of the Stigonematales even though it never displays a branched filamentous habit characteristic of the other genera in this order (Fig. 7). It does however produce typical, short-chained, motile hormogonia that differentiate into multiseriate-cell aggregates that appear more unicellular than filamentous.

The genera *Fischerella* and *Hapalosiphon* are both capable of true branching (Fig. 7). In *Fischerella* the cells of the lateral branches differ in size from the cells in the main axis and are uniseriate, whereas the main axis may become multiseriate. In *Hapalosiphon* both the main axis and lateral branches are uniseriate and composed of similar sized cells.

Members of the genus *Stigonema* are also capable of true branching. *Stigonema* is distinguished from *Fischerella* and *Hapalosiphon* by the complexity of its thallus structure resulting from an ability to form both multiseriate and uniseriate branches. Only one strain of *Stigonema minutum* has been cultured (Zehnder, 1985). There are also a number of genera in this order that have not yet been cultured which will make fascinating subjects for future study (Geitler, 1932).

Representatives of the genera *Anabaena, Cylindrospermum, Calothrix,* and *Fischerella* are illustrated in The Phototraphic Prokaryotes in the second edition, Figs. 14–17.

CHAPTER 2.2

The Cyanobacteria—Ecology, Physiology and Molecular Genetics

YEHUDA COHEN AND MICHAEL GUREVITZ

Introduction

The cyanobacteria and prochloroaceae are the only prokaryotic groups that share the use of photosystems I and II and hence the ability to carry out oxygenic photosynthesis with all photosynthetic eukaryotic organisms (Stanier, 1977). The structure of the reaction center complexes seems to be evolutionarily conserved in all these organisms, but there is a large diversity in their antenna chlorophyll complexes (Glazer, 1983). Cyanobacteria are unique since they are also capable of anaerobic metabolism, and several groups among the cyanobacteria share with the prokaryotic anoxygenic phototrophic bacteria the ability to perform anoxygenic photosynthesis using reduced electron donors (Cohen et al., 1975a; Padan and Cohen, 1982; Cohen et al., 1986; de Wit and van Gemerden, 1989; Garcia-Pichel and Castenholz, 1990). They also share with many archaebacteria the ability to use elemental sulfur for anaerobic dark respiration (Oren and Shilo, 1979).

Cyanobacteria are a diverse group of oxygenic photosynthetic prokaryotes, exhibiting versatile physiology and wide ecological tolerance that contribute to their competitive success over broad spectrum of environments both planktonic and benthic (Shilo, 1989). They are dominant in a broad spectrum of terrestrial habitats, including deserts, where they are found as endoliths in the antarctic dry valleys and cold deserts (reference is not an exact matchFriedman, 1982); hot deserts in the Sahel (Potts and Friedmann, 1981); tropical rain forests; and mangrove swamps. Planktonic cyanobacterial blooms are common in freshwater bodies, especially where eutrophic conditions exist (hyperscums of *Microcystis aeruginosa* over 1 m thick have been reported, Zohary and Cohen, 1991), as well as in oligotrophic oceans (where *Synechococcus* spp. may account for 50% of the chlorophyll *a* biomass, Waterbury et al., 1979; Olson et al., 1990). Among this widespread group of photosynthetic prokaryotes are species that are able to grow as aerobic photoautotrophs; anaerobic photoautotrophs using either H_2S, thiosulfate, or H_2 as alternative electron donors; photoheterotrophs; chemoheterotrophs; and as anaerobic or aerobic dinitrogen fixers (Allen, 1985; Paerl et al., 1989; Stal et al., 1989b).

Historically, cyanobacteria were long classified as blue-green algae according to the Botanical Code, and it was only in the eighth addition of *Bergey's Manual of Determinative Bacteriology* (Buchanan and Gibbons, 1974) that they were first assigned to a separate division of the prokaryotes.

Cyanobacteria are unique in that they are Gram-negative prokaryotes and yet perform oxygenic photosynthesis very similar to that of higher plants. Thus, they may serve as a model system to resolve biological questions difficult to approach in higher plants, and they can be target organisms for research not directly related to photosynthesis. Hence, not only questions associated with the photosynthetic apparatus and function, carbon fixation, light-regulated gene expression, but also cell differentiation and resistance to environmental factors or stress may be easier to address with the power of molecular genetics in cyanobacteria, rather than in higher plants.

The key to the genetic study and manipulation of cyanobacteria is the development of a transformation system (either natural or artificial) for DNA uptake. Such a system of cellular competence could be used to internalize exogenous DNA with or without a special treatment to the recipient cells prior to their incubation with the donor DNA. The majority of cyanobacterial strains capable of DNA-mediated transformation possess physiological, or natural, competence for DNA uptake. The mechanism involved in such a process is still unknown but the phenomenon has been extensively used to transform cyanobacterial cells either chromosomally or with plasmids.

Chromosomal transformation is achieved by recombination and internalization of donor chromosomal DNA with homologous DNA in

---

the recipient cell. By using donor DNA that has been subjected prior to the transformation to either in vivo mutagenesis or to recombinant DNA manipulations in vitro, it is possible to create and easily select for mutants according to their phenotype or a genetic marker. It is thus possible to produce insertion or deletion mutations in cyanobacterial genomes, permitting the analysis of gene structure, function, and organization.

Plasmid transformation involves the introduction of a plasmid DNA molecule able to replicate in the recipient cell. This allows development of plasmid vectors for cyanobacteria that can be used to produce cyanobacterial partial diploids or meroploids, as well as to introduce foreign genes whose function is analyzed in the recipient cell.

Cyanobacteria can also be transformed with nonreplicating plasmids containing chromosomal-homologous sequences. In such a case, except for homologous recombination between the plasmid and the chromosome, another outcome may be the incorporation of the entire plasmid into the cyanobacterial chromosome if a single recombination event occurs between the homologous sequences. By constructing such mutants, it is possible to create heterogenotes in which a foreign mutant gene is tandemly placed next to the wild-type gene in the chromosome.

So far, only unicellular strains have been found to possess a natural competence for DNA uptake. However, the development of conjugal DNA-mediated transfer for filamentous cyanobacteria has circumvented this problem and opened a way to introduce genetic material into cells that were previously restricted for genetic transformation. The shuttle vectors developed for such transformation are capable of replicating in both *Escherichia coli*, in which DNA manipulations can be performed, and in the recipient cyanobacterium. Another way to introduce DNA into cyanobacteria could exploit cyanophages as candidate vectors. Despite the fact that several cyanophages have been described, no gene transduction has been reported in cyanobacteria.

Our present understanding of the ecology, physiology, and molecular genetics of cyanobacteria allows the exploration of the use of cyanobacteria for several biotechnological uses, such as the production of specific photosynthetic pigments and herbicides and the use of cyanobacteria for agricultural dinitrogen fixation.

Cyanobacterial Mats

Cyanobacterial mats are stratified benthic microbial communities in which cyanobacteria are dominant, developing at sediment-water interfaces in a wide spectrum of shallow aquatic systems. They form laminated multilayers (biofilms) embedded in copious amounts of polysaccharides excreted by the benthic microbial community (Krumbein et al., 1977). The laminated microbial community develops in response to chemical microgradients at the mat surface. Such gradients can be measured by the use of specific microelectrodes for pO_2, pH, and pS^{2-} (Jørgensen et al., 1979b, 1983; Revsbech et al., 1983; Revsbech and Jørgensen, 1986). Steep microgradients of oxygen from zero to 1000 μM, pH from 7.0 to over 11.0, and H_2S from zero to 500 μM can be found in the upper 2 mm of the cyanobacterial mat. These chemical microgradients are largely the result of intensive oxygenic photosynthesis, which takes place at the very surface of the cyanobacterial mat. Light is rapidly absorbed by the benthic cyanobacterial community, leading to a steep gradient of photosynthetically available light (Jørgensen et al., 1987; Jørgensen, 1989). Sulfide production and oxidation is tightly coupled to the excretion of organic photosynthates by the cyanobacteria, resulting in maximal rates of sulfate reduction within the photic zone at midday (Cohen, 1984b). The concomitant activities of oxygenic photosynthesis, together with anaerobic metabolism of anoxygenic photosynthesis by associated anoxygenic phototrophic bacteria, such as *Chloroflexus* spp., *Ectothiorhodosira*-like spp., and *Thiocapsa* spp. (Stolz, 1984; D'Amelio et al., 1987), as well as sulfate reduction (Jørgensen and Cohen, 1977), and methane production (Cohen, 1986), may be possible by H_2 production through photoreduction of water by the cyanobacteria at high light intensity and under CO_2 limitation. It is probably CO_2 limitation at the photosynthetically active zone of the cyanobacterial mat that causes isotope fractionation for $^{13}C/^{12}C$ in the organic matter in shallow-water hypersaline microbial mats to be relatively heavy (–4% to –11%) (Des Marais et al., 1989). Addition of CO_2 results in a drastic enhancement of the rate of CO_2 photoassimilation by the cyanobacterial mat community (Rothschild and Mancinelli, 1990).

Because the chemical microgradients are largely light-dependent (Cohen, 1984b), the cyanobacterial mat becomes completely anoxic at night and thus exposed to elevated H_2S concentration at about neutral pH. Cyanobacteria may cope with these diurnal fluctuations of oxygen and sulfide by either migrating vertically in the mat and thus avoiding the exposure to toxic levels of sulfide at lower light intensity (Castenholz, 1973; Richardson and Castenholz, 1989) or by shifting their photosynthetic mode to adapt to life under sulfide (Cohen, 1984a).

Highly developed cyanobacterial mats are common in hot springs at temperatures of less than 74°C and at pH levels above 5.0 (Castenholz, 1984; Ward et al., 1989), in alkaline lakes, and in marine (e.g., Bauld, 1984) and hypersaline ecosystems at salinities of up to 20% salt (Des Marais et al., 1989). Cyanobacterial mats at salinities lower than 4.5% rarely accumulate because they are heavily grazed by a variety of higher organisms. Only under extreme environmental conditions of elevated temperatures and/or high salinity do cyanobacterial mats accumulate (to over 1 m thick in in environments such as the hypersaline Solar Lake on the coast of the Gulf of Aqaba in Sinai; Krumbein et al., 1977).

Cyanobacterial mats are probably the oldest form of known life on earth, as shown by the oldest known microfossils which were found in lithified microbial mats (stromatolites) in Central Australia and have been dated at 3.56 billion years (Knoll, 1989). Stromatolites are the most dominant sedimentary structures in rocks throughout the Precambrian era, together with vast deposits of Banded Iron Formation, both of which are associated with widespread development of cyanobacterial mats. While most researchers agree that these sedimentary rocks are associated with the development of microbial mats, many dispute the interpretation of cyanobacterial mat communities, mainly because 16S rRNA analyses of cyanobacterial cultures suggest these organisms are more recently evolved (Woese, 1987; Turner et al., 1989).

Marine and hypersaline cyanobacterial communities are often covered with thin layers of eukaryotic diatoms, *Navicula*, *Nitzchia*, and *Amphora* spp. The cyanobacterial mats in marine and hypersaline environments consist primarily of the filamentous cyanobacteria *Microcoleus chthonoplastes*, *Oscillatoria limnetica*, *Phormidium* spp., *Oscillatoria* spp., *Lyngbia* spp., *Calotrix* spp., *Spirulina* spp., and *Schytonema* spp. They are often associated with a variety of unicellular cyanobacteria, of which the dominant types are *Synechococcus* spp., *Synechocystis* spp., *Pleurocapsa* spp., and *Dermocarpa* spp. (Jøorgensen et al., 1983; Stolz, 1984; D'Amelio et al., 1989). The unicellular forms are more abundant at salinities higher than 10%. These cyanobacterial communities occupy the photic zone, which may range from less than 2 mm to over 6 cm. These cyanobacteria are closely associated with a variety of anoxygenic phototrophs, many of which are not yet available in pure culture, including several morphotypes of the green gliding phototrophic bacteria (*Chloroflexus* spp.) and filamentous purple bacteria resembling *Ectothiorhodospira* (D'Amelio et al., 1987, 1989). Other anoxygenic phototrophic bacteria found in hypersaline mats include *Chromatium* spp., *Thiocapsa pfennigii*

(Stolz, 1984), and *Ectothiorhodospira halochloris* (Imhoff et al., 1978). The assemblage of the various anoxygenic phototrophic bacteria are found within the cyanobacterial layer or right below at the deeper part of the photic zone, where a distinct olive-green and/or purple layer can often be found. Right below this layer, a distinct microzone of chemotrophic *Beggiatoa* spp. and *Thioploca* spp. is characteristic for the chemocline, where both oxygen and sulfide coexist (D'Amelio et al., 1989).

In hot spring cyanobacterial mats, where chemical composition and temperature vary widely (Brock, 1978), cyanobacteria are excluded at temperatures above 74°C and at acidic pH (Brock, 1973). *Synechococcus lividus* forms a thick layer over a distinct accretion of *Chloroflexus auranticus* at temperatures of 74 to 60°C. Only at lower temperature can a deep brownish red, c-phycoerythrin-containing cyanobacterium, *Oscillatoria terebriformis*, be found. At temperatures below 45°C, the moderately thermophilic cyanobacteria *Phormidium, Pseudoanabaena, Synechococcus, Calotrix*, and *Mastigocladus laminosus* are found (Castenholz, 1984).

Nitrogen fixation was demonstrated in the mat-forming cyanobacteria *Oscillatoria limosa* (Stal and Krumbein, 1985; Stal et al., 1989) and *Microcoleus chthonoplastes* (Pearson et al., 1981).

Cyanobacterial mats developing in extreme conditions of elevated temperature or at high salinity are clearly laminated microbial communities that can serve as good models for the study of metabolic and genetic interactions in a multi-layered microbial biofilm. The various aspects of the ecology, physiology, and molecular biology of both natural communities of cyanobacterial mats as well as isolated pure cultures from microbial mats are discussed in Cohen et al. (1984b) and Cohen and Rosenberg (1989).

Anoxygenic Photosynthesis in Cyanobacteria

Cyanobacteria are often found to develop in environments rich in sulfide. These environment are also rich in available nitrogen and phosphate and CO_2 sources as the result of the anaerobic breakdown of organic matter (Cohen, 1984b). Sulfidic environments may also provide a low-oxygen environment suitable for an optimal operation of ribulose bisphosphate carboxylase (rubisco), the key enzyme of CO_2 photoassimilation (Avron, 1989). Yet H_2S is highly toxic and brief exposure to low sulfide concentrations may irreversibly inhibit most eukaryotic phototrophs. Even sulfide-producing prokaryotes, such as sul-

fate-reducing bacteria, are inhibited at elevated H₂S concentrations.

Nakamura (1938) was the first to observe growth of *Oscillatoria* in 1 mM H_2S without the detection of oxygen production and the deposition of sulfur in the cells, suggesting that H_2S was being used as an electron donor for CO_2 photoassimilation. Cohen et al. (1975a, 1975b) confirmed this observation in cultures of *Oscillatoria limnetica* isolated from the hypolimnion of a stratified hypersaline lake in Sinai, where this cyanobacterium was the dominant phototroph at up to 3 mM H_2S (Cohen et al., 1977). This cyanobacterium was found to carry out anoxygenic CO_2 photoassimilation with sulfide as an alternative electron donor to water in a photosystem I (PS-I)-driven reaction similar to that carried out by anoxygenic photosynthetic bacteria. Assimilation of CO_2 in the presence of sulfide was found to involve a stoichiometric oxidation of H_2S to elemental sulfur, which was deposited outside the cells (Cohen et al., 1975). This process was independent of photosystem II (PS-II), which was found to be fully inhibited at low sulfide concentrations of 0.1–0.2 mM. Anoxygenic photosynthesis in this organism required an induction period of 2 h in the light and in the presence of sulfide. Photosynthetic efficiency of H_2S-driven anoxygenic photosynthesis was found to be even higher than oxygenic photosynthesis, especially when exposed to red light, and could sustain growth at a doubling rate of about 6 h (Oren et al., 1977; Oren and Padan, 1978). A specific sulfide-quinone reductase was needed for the induction of anoxygenic photosynthesis (Arieli et al., 1991). These workers demonstrated that photosynthetic thylakoids isolated from *Oscillatoria limnetica* grown under sulfide have the capacity in the dark to catalyze electron transfer from sulfide to externally added quinones. They therefore proposed that a membrane-bound sulfide-quinone reductase is the sulfide-induced factor which enabled the use of sulfide for anoxygenic photosynthesis in *Oscillatoria limnetica*. The detailed molecular mechanism of electron transport coupled to proton translocation in cytochrome b_6f/bc_1 complexes is not yet understood, but cytochrome b_6f may be involved in anoxygenic photosynthesis. Arieli et al. 1991 hypothesize the existence of several electron carriers which mediate electron transfer from different donors to the plastoquinone-b_6f complexes. These carriers are thought to have a common site, which interacts with the plastoquinone or cytochrome b_6, as well as a different site, which interacts with the various different electron donors.

Sulfide was found to be oxidized to thiosulfate in *Microcoleus chthonoplastes* (de Wit and van Gemerden, 1987, 1989). Thiosulfate was found to be an electron donor (Castenholz and Utkilen, 1984). Sulfide could be replaced with molecular hydrogen as another alternative electron donor for H_2-dependent photoreduction of CO_2 in another PS-I-dependent anoxygenic photosynthesis in *Oscillatoria limnetica* and *Aphanotheca halophytica* (Belkin et al., 1988).

Depending on the reaction conditions, the electrons from sulfide in *O. limnetica* may be channelled to CO_2 photoassimilation, dinitrogen fixation, or hydrogen evolution under CO_2 limitation (Belkin, Shahak, and Padan, 1988). Sulfide stimulation of hydrogen production was also found in *Nostoc muscorum* by Weisshaar and Boeger (1983).

Cyanobacteria may evolve different mechanisms to grow in the presence of sulfide. *Oscillatoria* spp. grown in sulfide-rich hot springs in Utah were found to be able to carry out oxygenic photosynthesis even in the presence of 2 mM sulfide (Cohen et al., 1986), and similar behavior was found in cyanobacteria grown in sulfide-rich hot springs in New Zealand. In these organisms, PS-II is considerably less sensitive to sulfide toxicity compared to *Oscillatoria limnetica,* but the mechanism of sulfide detoxification is not as yet known. These organisms do not have the capacity for anoxygenic photosynthesis.

Microcoleus chthonoplastes, a cosmopolitan mat-building cyanobacterium found in marine and hypersaline environments, has been demonstrated to have both the capacity to carry out oxygenic photosynthesis at 1 mM sulfide concentration and to be able to carry out anoxygenic photosynthesis using sulfide as an electron donor (Cohen et al., 1986; Jorgensen et al., 1986; de Wit and van Gemerden, 1989).

Other Anaerobic Metabolism Pathways in Cyanobacteria

Nitrogen Fixation

Anaerobic conditions enhance dinitrogen fixation in cyanobacteria because of the toxicity of oxygen to the nitrogenase enzyme. Some cyanobacteria have developed specialized cells called heterocysts where PS-II is absent, but many cyanobacteria can fix dinitrogen aerobically without the need for heterocysts. Two main mechanisms for keeping oxygen away from the nitrogenase sites have been described: 1) Formation of oxygen-poor microniches in aggregates of cyanobacteria, where PS-II and oxygen evolution take place in the periphery of the aggregate while dinitrogen fixation occurs in the center of the cyanobacterial clump. Such a mechanism was described for aggregates of *Trichodesmium* (taxonomically, *Oscillatoria*), a widespread marine

filamentous cyanobacterium common in nitrogen-poor tropical oceans (Paerl et al., 1989b; Currin et al., 1990). Using immunoassays, Paerl and his colleagues have shown the localization of nitrogenase in these organisms in the center of the *Trichodesmium* aggregate (Paerl et al., 1989a). 2) Temporal separation of oxygen evolution and nitrogenase activity was demonstrated in several unicellular cyanobacteria, including the widespread picoplanktonic *Synechococcus* in tropical oceans (Mitsui et al., 1986) and the mat-forming cyanobacterium *Oscillatoria limosa* (Stal et al., 1989).

Anaerobic Dark Respiration and Fermentation

Several mat-forming cyanobacteria have been found to survive better under anaerobic conditions in the dark. This phenomenon was described for mats of *Microcoleus chthonoplastes* (Jørgensen et al., 1988), *Oscillatoria terebriformis* (Richardson and Castenholz, 1987), and *O. limosa* (Stal et al., 1989). Glycogen was found to be fermented in a heterofermentative mode producing equal amounts of lactate, ethanol, and CO_2 in *O. limosa* (Stal et al., 1989), while only lactate was found in anaerobic fermentation in *O. limnetica* (Oren and Shilo, 1979). Acetate production in anerobically grown *O. limosa* in the dark was postulated to be the result of anerobic degradation of trehalose (Stal et al., 1989), which serves as an osmolite in several cyanobacteria (Hershkovitz et al., 1991).

Addition of elemental sulfur to anaerobically grown *O. limnetica* and *O. limosa* resulted in anaerobic respiration and reduction of the elemental sulfur to sulfide in the dark (Oren and Shilo, 1979; Stal et al., 1989). The reduction of elemental sulfur in the dark to sulfide was demonstrated in the chemocline of Solar Lake, Sinai (Jørgensen et al., 1979), where a bloom of the unicellular cyanobacterium *Dactylococcopsis salina* (Walsby et al., 1983; van Rijn and Cohen, 1983) and *Aphanotheca halophytica* were dominant.

Given the widespread distribution of cyanobacteria in a spectrum of sulfide-rich environments, such as hot springs and cyanobacterial mats in marine and hypersaline environments, a variety of other low-redox, sulfur-dependent metabolic pathways are expected to be discovered in the future.

Cyanobacterial DNA

Like other prokaryotes, cyanobacteria contain two types of DNA, chromosomal DNA and smaller, autonomous, extrachromosomal molecules. Both types of DNA can be used for gene transfer and manipulation, each having both advantages and disadvantages. In both instances, transformability of the cell is a prerequisite for gene manipulations. The introduction of foreign DNA can be monitored either by following a genetic marker or by observing some phenotypic alteration indicating a successful transformation. Targeting of the foreign DNA into specific sites in the acceptor DNA and the copy number of the introduced gene may both be of great importance for its expression. Mobilizing DNA sequences into or out of a cyanobacterial cell is not always easier when using extrachromosomal self-replicating molecules. So far, no specific function has been assigned to cyanobacterial plasmids, and in some instances, curing the cells of their plasmids did not have any deleterious effect on the cells, nor was their viability harmed. Nevertheless, various procedures for transforming cyanobacteria have been developed using both types of cyanobacterial DNA.

Genome Size

The genome size of 128 strains representing all major taxonomic groups of cyanobacteria has been measured from the kinetics of renaturation of DNA. The range of size is between 1.6×10^9 Da in the unicellular strains, which is comparable in size to those of other bacterial genomes (Gillis et al., 1970; Wallace and Morovitz, 1973), and 8.6×10^9 Da, in the larger filamentous strains, which greatly exceeds the largest genome previously described in prokaryotes. Even though a larger genome might be anticipated in organisms capable of fixing nitrogen and exhibiting morphological differentiation, the great excess of DNA in these strains raises the possibility that some DNA sequences do not possess a coding capacity (Doolittle, 1979). Genetic mapping of the chromosome of cyanobacteria may shed light on such enigmas as well as establish a physical map of the chromosome. Wolk and coworkers have initiated such a study with *Anabaena variabilis* by producing a set of serially overlapping cosmid clones (Herrero and Wolk, 1986).

The genome sizes of cyanobacteria are discontinuously distributed into four distinct groups with means of 2.2×10^9, 3.6×10^9, 5.0×10^9, and 7.4×10^9 Da. This suggests that genome evolution in cyanobacteria occurred by a series of duplications of a small ancestral genome (Herdman et al., 1979).

Cyanobacteria contain several identical chromosomes in each cell (Williams, 1988), which suggests the possibility of interactions between them. Even though genome interaction seems very likely, no direct molecular evidence for

recombination between chromosomes in cyanobacteria has been documented. An intrachromosomal gene conversion mechanism involving the *psb*A gene family in *Synechococcus* PCC 7942 was elucidated by Brusslan and Haselkorn (personal communication). Interchromosomal recombination was observed in *Synechocystis* PCC 6803 by Gurevitz and co-workers (unpublished observations). Thus, the general assumption favors the existence of such mechanisms in cyanobacteria. The *rec*A gene was identified in some cyanobacterial species (Murphy et al., 1987), and in many instances, recombination between chromosomal DNA and plasmid DNA has been proposed. To minimize fortuitous results, this phenomenon should be taken into account whenever introduction of foreign or engineered genes into cyanobacteria is considered.

Plasmids

The existence of nonchromosomal DNA molecules in cyanobacteria was first observed in *Anacystis nidulans* (*Synechococcus* sp.) (Asato and Ginoza, 1973). Ever since, it has been evident that nearly all cyanobacteria possess endogenous plasmids (Rebiere et al., 1986), suggesting that it might be feasible to use these molecules as tools in molecular genetic studies. However, no function encoded by cyanobacterial plasmids has been identified so far, and the regulatory mechanism of their replication is still unknown. Several workers have tried to attribute various functions to plasmids, such as gas vacuolation (Walsby, 1977), toxin production (Hauman, 1981; Schwabe et al., 1988), resistance to high salt concentrations or heavy metals (Van den Hondel et al., 1979), resistance to antibiotics (Flores and Wolk, 1985), and synthesis of restriction/modification enzymes (Whitehead and Brown, 1985). It was observed that spontaneous loss of plasmids from different unicellular strains, such as *Synechococcus* sp. PCC 6301 and 73109 (Whitehead and Brown, 1985) and *Synechocystis* sp. PCC 6803 (Tandeau de Marsac and Houmard, 1987), could occur without causing any obvious phenotypic change.

Still, several research groups have produced various cloning vectors or shuttle vectors (*E. coli*-cyanobacterium) by utilizing these self-replicating molecules. Nevertheless, this approach is limited since the parameters related to mechanisms involved in plasmid replication and control of plasmid copy number in cyanobacteria remain obscure.

The number of autonomous plasmids per cyanobacterial cell may vary from one up to eight, with sizes ranging from 1.3 kb to about 130 kb (Tandeau de Marsac and Houmard, 1987).

In a few instances, different strains of cyanobacteria possess plasmids of identical size and endonucleolytic digestion pattern (Walsby, 1977; Hauman, 1981; Van den Hondel et al., 1979) or sequence homologies (Schwabe et al., 1988). Since some of these strains are of different geographical origins, an implication can be made that interspecific or even intergeneric plasmid transfer may occur in nature.

In other cases, multimeric forms of a single plasmid species were elucidated by digestion with restriction enzymes. Reaston et al. 1980 found in *Nostoc* sp. PCC 7524, three plasmids, pDU1, pDU2, and pDU3 (6.1, 11.8, and 37.3 kb respectively), where pDU2 is a dimeric form of pDU1. This raises questions in regard to the function and preservation of such forms in the cell, particularly if an active recombination mechanism followed by segregation is considered. Even though the plasmids obtained from different cyanobacterial species are generally similar when purified by different researchers, there are exceptions that in few instances were attributed in part to the extraction protocol used in the various laboratories. However, the very extensively studied cyanobacterium *Calothrix* sp. PCC 7601 (*Fremyella diplosiphon*) is a real exception since different restriction patterns and different plasmid numbers were obtained in various laboratories (Simon, 1978; Bogorad et al., 1983; Tandeau de Marsac and Houmard, 1987). These variations could not be explained or related to phenotypic changes of the cells. However, these results, together with previous observations (Tandeau de Marsac, 1983), that spontaneous pigment mutants arise with high frequency (10^{-3} to 10^{-4}) in this organism led the de Marsac group (Tandeau de Marsac and Houmard, 1987) to suggest the existence of mobile genetic elements in the *Calothrix* strain. So far, whether these elements might be transposons, insertion elements, or Mu-type phages has not been determined. If mobile DNA elements do exist, one would expect high frequencies of genome rearrangements in cyanobacteria. Nevertheless, the only rearrangement documented so far has been the well-analyzed rearrangement of the *nif* region in the filamentous dinitrogen-fixing strain *Anabaena* sp. PCC 7120, which accompanies the differentiation of vegetative cells into heterocysts (Golden et al., 1985a, 1985b).

Restriction/Modification of Cyanobacterial DNA

Chromosomal DNA from various unicellular and filamentous cyanobacteria is considered highly resistant to cleavage by a number of restriction endonucleases, although only a mod-

est repertoire of restriction enzymes was found in these organisms (Van den Honel et al., 1983; Herrero et al., 1984; Lambert and Carr, 1984). Still, more than 50 strains from nine different genera contain from one to five restriction endonucleases (Tandeau de Marsac and Houmard, 1987). Some of the endonucleases, such as the AvaI or AvaII type, are isoschizomers that are widely distributed among different genera. Presumably, this may be related to a common evolutionary origin. Together with their modification methylase associates, they could be acquired by the transfer of plasmid- or cyanophage-encoded genes. However, no correlation among the plasmid content of cyanobacterial strains, their phage sensitivity, and their restriction endonuclease content has been observed.

A similar pattern of DNA modification was found by Lambert and Carr (1984) in diverse filamentous strains that contain (*Gleotrichia* and *Plectonema*) or do not contain (*Nostoc*) different types of restriction endonucleases. Concomitantly, they observed a great variation in the susceptibility of genomes from five unicellular strains, to cleavage by a group of restriction enzymes. By using isoschizomers, Geier and Modrich (1979) were able to demonstrate that DNA resistance to cleavage could originate either from a host-controlled restriction/modification system, as found in other groups of bacteria, or due to a *dam* (DNA adenine methylase) enzyme. Examples of possible restriction/modification systems operating in vivo were depicted for *Anabaena* sp. PCC 7937 (Currier and Wolk, 1979) and for *Synechococcus* sp. PCC 6301 (Szekers, 1981; Szekers et al., 1983). Cyanophage N-1 derived from *Anabaena* sp. PCC 7120 was able to form plaques on *Anabaena* sp. PCC 7937 at a very low efficiency, but the surviving progeny of the phage increased its plaque formation efficiency when reinfecting the same strain (*Anabaena* sp. PCC 7937). The conclusion from this experiment was that the cyanophage N-1 DNA that escaped restriction in *Anabaena* sp. PCC 7937 could have been modified by the host cell. On the other hand, in experiments performed in vitro by Szekers (1981), it was shown that DNA from *Synechococcus* sp. PCC 6301 was cleaved by an endonuclease produced by AS-1 cyanophage-infected cells. Moreover, the cyanophage DNA was unprotected after cloning in a plasmid vector propagated in an *E. coli* strain. These results indicated that a restriction/modification system was induced in *Synechococcus* sp. PCC 6301 by AS-1 cyanophage; the modification mechanism involved remains unknown.

Another example is the modification enzyme M.NspMACI, which was purified from *Nostoc* sp. PCC 8009. This strain normally contains an isoschizomer of BglII (Reaston and Carr, 1985) called NspMACI, which is unable to cleave DNA previously modified by M.NspMACI while BglII does. This is an indication that the modification sites affected by M.BglII and M.NspMACI are different.

Several explanations for the resistance to cleavage of cyanobacterial DNA were proposed (Lambert and Carr, 1984; Jager and Potts, 1988), including the presence of specific inhibitors like DNA-binding proteins, unusual bases (other than MeC and MeA), and the absence of specific recognition sequences in the genomic DNA of certain cyanobacteria. Whether such modification processes play a role in cyanobacterial gene expression and cell differentiation requires further examination.

Genetic Recombination

Cyanobacteria are susceptible to ultraviolet (UV) irradiation, and therefore they are expected to possess an efficient mechanism to permit repair of UV-induced damage (by genetic exchange and gap-filling). The occurrence of homologous recombination in cyanobacteria explains the high efficiency of foreign DNA incorporation into the genome of unicellular strains like *Synechococcus* PCC 7942 and *Synechocystis* PCC 6803. Recombination activity in cyanobacteria is advantageous for genetic engineering when utilized for the internalization of exogenous DNA into the chromosome. It may be considered a disadvantage when such activity may destroy engineered constructs mobilized into cyanobacteria via plasmid vectors. On one hand, homologous recombination has become a useful way to achieve insertions or deletions at various genes. However, one of the major problems associated with the introduction of cloning vehicles into cyanobacteria is recombination between vector and resident plasmids. For the stable maintenance of hybrid plasmids in *Synechocystis* PCC 6803, some Rec⁻ mutants deficient in homologous recombination were employed. In these mutants, no transformation with either chromosomal markers or integrative vectors occurred, while the autonomously replicative vector pSE76 transformed such recipients at high frequency (Shestakov et al., 1985). Although all transformable cyanobacteria are recombination-proficient, no documentation in respect to the molecular mechanism involved has been reported. However, the *rec*A gene from *Synechococcus* PCC 7002 was identified, and its sequence determined (Murphy et al., 1987). This problem is significant and should be addressed when planning experiments of complementation, of DNA transfer (when recombination activity should be avoided), and of studies related to

dominance of genes (Haselkorn, 1985). Cyanobacteria possess several identical chromosomes per cell. When transformed with exogenous DNA, in most cases, all the chromosomes will contain the foreign DNA after a few cell cycles, due to segregation. Whether this is followed by interchromosomal gene conversion is still unknown. A concomitant unsolved question is related to the possible occurrence of intrachromosomal gene conversion in cyanobacteria. In addition, it is still unknown whether there exists a mechanism for gene duplication or amplification in cyanobacteria. It is suspected that such a mechanism does exist, particularly as a response to environmental stimuli like an excess of light. Such processes rely on recombination activity, and their better understanding is obviously necessary.

Gene Transfer in Cyanobacteria

To mobilize genetic material into cyanobacteria, the target cyanobacterium should: 1) be transformable by exogenous DNA; 2) have no host restriction; 3) be Rec⁻ when stabilization of autonomous vector is required; 4) allow the generation of meroploids; 5) express genetic markers; and 6) recognize regulatory elements required for transcriptional and translational activities.

A few unicellular strains were found to be competent for genetic transformation and can be readily transformed with either circular or linear DNA. The donor DNA may contain a cyanobacterial origin of replication (*ori*), thus becoming a replicon within the transformed cells, or be lacking an *ori*. In either case, the fate of this DNA inside the transformed cell (recipient) may be different. A more sophisticated approach was required for the development of gene transfer mechanisms in filamentous strains.

A recombinant plasmid, pCH1 (Ap^R), derived from the endogenous pUH24 plasmid of *Synechococcus* PCC 7942 and possessing the Tn*901* transposon, was the first used by Van den Hondel and co-workers (1980) to transform *Synechocystis* PCC 7942. Transformed cyanobacteria grew in presence of ampicillin but the vectors used were unable to replicate in *E. coli*, which limited their construction and utilization. Since recombinant DNA technology has been largely developed using *E. coli*, it became a great advantage to have shuttle vectors capable of replicating both in *E. coli* and in cyanobacteria. A few cyanobacterial plasmids were used to construct a variety of shuttle vectors (Pouwels et al., 1985; Tandeau de Marsac and Houmard, 1987).

The pCH1 plasmid was further used to create a deletion derivative (pUC1) lacking one of the

inverted repeats of Tn*901*. This construction stabilized the marker and prevented any further transpositions. From pUC1 (Ap^R), a family of shuttle vectors was prepared by Van Arkel and colleagues (Kuhlemeier et al., 1981) by combining it with the *E. coli* plasmid pACYC184 (Cm^R). The resulting shuttle vector pUC104 (Ap^R, Cm^R), was stably maintained in *Synechococcus* PCC 7942. Shuttle vector pUC104 purified from *E. coli* was less efficient in transforming the cyanobacterium as compared to pUC104 purified from the cyanobacterium itself. It was hypothesized that there was a difference in their post-replicational DNA modifications (Kuhlmeier et al., 1981). This idea was supported by Gallagher and Burke (1985), who found a sequence-specific endonuclease, AniI, that could restrict foreign DNA. Plasmid pUC104 and lambda DNA were combined to construct a cosmid vector (pPUC29) capable of being packaged in vitro into lambda phage particles and of being introduced into *E. coli* by infection. A further step to optimize the host-vector system for gene cloning in *Synechococcus* PCC 7942 was carried out by Kuhlemeier et al. 1983, who isolated a host strain (R2-SPc) cured of the endogenous plasmid pUH24. A new construct, pUC303, has allowed cloning of several genes, including genes involved with nitrate reductase activity.

A limitation to gene cloning in autonomously replicating vectors may arise from recombination between two homologous genes located in the plasmid and in the chromosome. This limitation can be avoided by dual selection for both the vector and for the chromosomal insert (Kuhlemeier et al., 1985).

Other shuttle vectors for *Synechococcus* PCC 7942 were constructed with pUH24 plasmid and *E. coli* plasmid of the pBR family. The hybrid shuttle vector pLS103 (Cm^R) was constructed from pUH24 and pBR322 by Sherman and Van de Putte (1982). The plasmid pECAN1 (Ap^R, Cm^R), based on pBR325, was constructed by Gendel et al. (1983).

Most of these shuttle vectors contain just a few unique cloning sites. Therefore, a series of hybrid plasmids with multiple cloning sites were produced by Gendel et al. (1983). These vectors, the pPLANB series, provided five or seven unique sites and were able to transform both *E. coli* and *Synechococcus* PCC 7942 with high frequency (10⁻⁵ transformants/cell). Similarly, Lau and Straus (1985) constructed several small, versatile, shuttle vectors: Plasmid pXB7 (Ap^R) with 10 unique cloning sites; pECAN8 (Ap^R), with four sites within the *lac*Z gene, which permits easy detection of recombinants in the presence of X-gal in some *E. coli* strains and pKBX (Km^R) with 10 cloning sites.

Since the large plasmid of *Synechococcus* PCC 7942, pUH25, contains an origin of replication compatible with that of pUH24, Laudenbach et al. (1985) constructed the pANLO1a and pANLO1b shuttle vectors. Cotransformation with both types of replicons allows simultaneous cloning of foreign genes into the cyanobacterium.

Although great attention was directed towards the cyanobacterium *Synechococcus* PCC 7942, hybrid plasmids were constructed with the small, cryptic plasmid pAQ1 from *Agmenellum quadruplicatum* PR-6 as well. Buzby et al. (1983) produced the pAQE2 and pAQE10 from pAQ1 and pBR322 and pBR325 respectively. The PR-6 strain contains the restriction enzyme AquI (AvaI) and, as demonstrated with the R-2 strain, shuttle vectors purified from PR-6 had higher transformation efficiencies than vectors propagated in *E. coli*. It is likely that the cyanobacterial DNA was modified to resist AquI. A significant difference between PR-6 and R-2 strains is the fact that dimeric and trimeric forms of biphasic plasmids yielded higher transformation frequencies than the analogous monomeric forms (Buzby et al., 1983). By contrast, in R2 strain, monomers are more efficient for transformation. The shuttle vector pAQE17 constructed by Buzby et al. (1985) was used to express allophycocyanin genes from the cyanelle *Cyanophora paradoxa* in *Synechococcus* PCC 7002.

The similarity of the photosynthetic apparatus between cyanobacteria and higher plants is of great advantage for a molecular genetic approach to various constituents involved in this system. Thus, an heterotrophic organism could be beneficial when photosynthetic gene manipulation is required without deleterious effects on the investigated organism. Since the cyanobacterium *Synechocystis* PCC 6803 is a facultative photoheterotroph and amenable for genetic transformation, measures to develop a host-vector system with this organism were taken. The small endogenous plasmid, pSS2, derived from this strain was used to create shuttle cloning vectors (Shestakov et al., 1985; Chauvat et al., 1986). The plasmid pSE176 (Cm^R, Km^R), was constructed from pSS2, pACYC184, pUC4K and contained several restriction sites at the Km^R region plus the EcoRI site in the Cm^R gene. Chauvat and co-workers (1986) have also used pSS2 but with pACYC177 and constructed the hybrid plasmid pFCLV7 (Cm^R, Km^R).

Attempts to transfer plasmids of *E. coli* into cyanobacteria were unsuccessful, probably due to the fact that the origin of replication of these plasmids was not recognized by cyanobacterial replication factors. However, McFadden and coworkers reported the incorporation of pBR322 plasmid into permeaplasts of *Synechococcus* PCC 6301 (Daniell et al., 1986). Permea-plasts are potentially viable cells with high permeability and capacity for cell-wall regeneration. Therefore, they may take up DNA at elevated ratios and subsequently repair and divide. In another experiment, this group demonstrated the uptake and expression of foreign DNA within whole cells of *Synechococcus* PCC 6301 (McFadden and Daniell, 1988). The mechanism involved in the incorporation and expression of the foreign DNA in these cyanobacteria has to be clarified.

A simple method to introduce foreign DNA into the chromosome of unicellular cyanobacteria was developed by Williams and Szalay (1983). They constructed chimeric DNA in an *E. coli* vector consisting of a DNA fragment derived from *Synechococcus* PCC 7942 that had been interrupted by the foreign (donor) DNA fragment aimed for introduction into the cyanobacterium. This construct could propagate in *E. coli* and transform cyanobacteria. The transformation was achieved via double recombination between homologous chromosomal and plasmid DNA sequences. This allows site-directed insertion of foreign DNA into the cyanobacterial chromosome. Addition of a selectable marker to the foreign DNA sequence enabled an easy selection of recombinant cells. Furthermore, in a case where a single recombination event took place, the entire vector could integrate into the chromosome. Distinction between both cases could be achieved by growing the transformants in the presence of one antibiotic (double recombination) or two antibiotics (single recombination). This method was adapted for *Synechocystis* PCC 6803 (Williams, 1988; Shestakov et al., 1985) and is currently widely utilized for studying a variety of cyanobacterial genes via their insertional inactivation, deletion, or modification, or the expression of foreign genes in cyanobacteria.

DNA from *E. coli* can be transferred into unicellular cyanobacteria in various ways that depend on the natural competence of the recipient strains. Some of the filamentous strains, such as *Anabaena* and *Nostoc,* possess unique systems related to differentiation and nitrogen fixation, which are very attractive for molecular studies. Unfortunately, the amenability of these systems to genetic manipulations is limited. For such strains, a gene-transfer system is of great advantage. Wolk and co-workers developed a very elegant conjugal system for transfer of exogenous DNA into *Anabaena* PCC 7120 (Elhai and Wolk, 1988). Three elements were required for the conjugation process: 1) a shuttle vector capable of replicating in *E. coli* cells and cyanobacteria which carries a genetic marker expressible in cyanobacteria and without too many AvaI and AvaII restriction sites; 2) a colicin K or colicin D

plasmid capable of mobilizing the shuttle vector in *trans*; and 3) an IncP plasmid, such as RP4, R702, R751, and R7K, capable of mediating the transfer of DNA into a wide range of Gram-negative bacteria including cyanobacteria. This process necessitates conjugal contact since the DNA is transferred via the pili of the conjugants. Practicably, a colicin-containing strain of *E. coli* is transformed with the shuttle plasmid, then mated with the RP4-containing *E. coli* strain. The mating mixture is put on top of the recipient cyanobacteria and transferred after one day to selective medium. Green recombinant colonies can be detected within 10 days.

The DNA transfer by conjugation method has been applied to other strains as well. Bullerjahn and Sherman (1985) constructed a plasmid containing the colE1 *ori*, RP4 *tra* functions, and transposon Tn*501* (conferring resistance to mercuric ions). In *E. coli*, low concentrations of Hg^{2+} promote transposition and the same phenomenon is seen in *Synechocystis* PCC 6714; there, a low level of Hg^{2+} present during conjugation resulted in a fivefold increase in the frequency of obtaining Hg^{2+}-resistant exconjugants. The integration of Tn*501* into the cyanobacterial chromosome was verified by Southern blotting. This demonstrated the feasibility of using the conjugal DNA-transfer method with unicellular cyanobacteria.

Isolation of Cyanobacterial Genes

To analyze gene structure and function, it is crucial to isolate the gene of interest. The following methods have been employed for the isolation of cyanobacterial genes in recent years.

Direct Cloning by Phenotypic Complementation

This method utilizes the phenotypic complementation of *Escherichia coli* or cyanobacterial mutants. The approach involves selection with mutants maintained under permissive growth conditions, e.g., either permissive temperature for temperature-sensitive mutations or photo-heterotrophic or heterotrophic conditions for strains capable of these metabolic modes. Shotgun-cloned genomic DNA fragments from the wild-type strain can be introduced into the mutant by using a suitable vector. After a certain period under nonselective conditions to allow expression of marker genes associated with the introduced DNA, the cells are shifted to nonpermissive, selective conditions. Complementary DNA fragments may then be identified due to their ability to allow growth of mutants under otherwise nonpermissive conditions. Comple-

mentation is then verified by isolation of the recombinant plasmid and its introduction into the mutant, which should result in the phenotypic difference previously observed.

This general strategy was employed in cloning DNA fragments conferring herbicide resistance in *Synechococcus* sp. PCC 7002 (Buzby et al., 1987) or DNA fragments that complemented photosynthetically impaired mutants of *Synechocystis* sp. PCC 6803 (Dzelzkalns and Bogorad, 1987). A distinct advantage of this method, that is not available in eukaryotic systems, is that it can be used to isolate DNA fragments complementing mutations in components very difficult to identify and isolate. Also, it can be used to identify genes whose products are not structural cell components and therefore cannot be detected in typical purified preparations of cellular fractions or complexes. In rare instances, genes encoding peripheral polypeptides to the photosynthetic process may be cloned by complementation of characterized mutations in *Escherichia coli*. As an example, this strategy was employed in cloning the phosphoenolpyruvate carboxylase (*pcc*) gene of *Synechococcus* sp. PCC 6301 (Kodaki et al., 1985), and the *gln*A gene of *Anabaena* sp. PCC 7120 (Fisher et al., 1981).

Heterologous Hybridization

This method for isolation of cyanobacterial genes uses heterologous hybridization with cloned DNA fragments from prokaryotes or eukaryotes. It is probably the most widely applied method simply because of the sequence conservation within many genes of various phylogenetic origins whose product is functionally similar, thus preserving common structural characteristics and DNA sequence.

In higher plants, many components of the photosynthetic apparatus are encoded by chloroplast genes. The complete nucleotide sequence of two chloroplast genomes was determined, and the open reading frames (ORFs) and unidentified reading frames (URFs) were extensively analyzed (Ohyama et al., 1986; Shinozaki et al., 1986). Also, many nuclear-encoded polypeptides which are part of the photosynthetic apparatus were identified, and their genes or cDNA clones isolated (Coruzzi et al., 1983; Smeekens et al., 1985a, 1985b; Tittgen et al., 1986). The availability of characterized genes or cDNA clones from higher plants that play a role in photosynthesis provides a ready source of materials for isolation and subsequent manipulation of their closely homologous cyanobacterial counterparts. A large number of genes encoding components of the photosynthetic apparatus in cyanobacteria were cloned using heterologous hybridizing

probes. In most cases, these probes were derived from cloned genes related to the chloroplast genome. For example: *psa*A and *psa*B (Cantrell and Bryant, 1987b; Lambert et al., 1985) related to the PS-I complex; *psb*A (Curtis and Haselkorn, 1984), *psb*B (Vermaas et al., 1987), *psb*C and *psb*D (Williams and Chisholm, 1987), *psb*E and *psb*F (Pakrasi et al., 1988) related to the PS-II complex; *pet*A, *pet*B, *pet*D (Kallas et al., 1987), and *pet*F (Van der Plas et al., 1986) related to the electron transfer chain between both photosystems; *atp*A, *atp*B, *atp*E, *atp*H, and *atp*I (Cozens and Walker, 1987; Curtis, 1987; Lambert et al., 1985) related to the ATP synthase complex in the photosynthetic membrane; and *rbc*L and *rbc*S (Curtis and Haselkorn, 1983; Shinozaki et al., 1983; Nierzwicky-Bauer et al., 1984; Shinozaki and Sugiura, 1983) for rubisco.

Low-stringency hybridization with heterologous probes was also successfully employed to isolate members of the phycobiliprotein or linker-polypeptide multigene families (Conley et al., 1985, 1986; Houmard et al., 1986; Mazel et al., 1986; Dubbs and Bryant, 1987; Belknap and Haselkorn, 1987; Lemaux and Grossman, 1985). With this type of hybridization, sometimes it is possible to obtain positive results with sequences whose polypeptide product is not immunologically cross-reactive (Dubbs and Bryant, 1987; Belknap and Haselkron, 1987).

Hybridization between *psb*A and *psb*D genes also occurs at very low stringency, although the gene products are antigenically distinct (Nixon et al., 1986). This hybridizable feature is usually dependent on several easy controlled factors: the probe should be a purified gene from an internal DNA fragment that is conserved in a functional and structural sense (Bryant and Tandeau de Marsac, 1988); stringent washes of blots should be avoided; low-ionic-strength washes at the hybridization temperature should not be performed. Under such conditions, even 45–55% nucleotide sequence similarities were sufficient for isolating genes (Dubbs and Bryant, 1987; Lemaux and Grossman, 1985; Murphy et al., 1987).

Synthetic Oligonucleotides

Cloning genes by utilization of synthetic oligonucleotide probes has become an increasingly popular approach in molecular biology. The advanced technology of DNA synthesis of fragments up to 100–200 base pairs in length allows screening of DNA libraries for a specific sequence even when only a small fragment of amino acid sequence of a protein product was determined.

However, due to the degeneracy of the genetic code, only in extremely rare instances will such experiments yield the desired DNA sequence. Three strategies can be employed to overcome this problem: In the first, if only a few potential sequences exist, all corresponding sequences can be synthesized and examined individually as hybridization probes. This strategy enabled the cloning of the *cpc*A gene of *Synechococcus* sp. PCC 7002 (De Lorimier et al., 1984) and the *cpc*B gene of *Cyanophora paradoxa* (Bryant et al., 1985). In the second, all potential oligonucleotide sequences are synthesized as a mixture. This mixture is radiolabeled and used for probing. The conditions for such hybridization should be determined empirically to allow only the putative perfect match to hybridize and to reduce strong competition by closely related sequences that might interfere or prevent detection of the desired signal or generate false positive signals. This strategy was used to clone genes such as the *cpc*B gene of *Synechococcus* sp. PCC 7002 (Pilot and Fox, 1984), the *pet*F gene encoding ferredoxin in *Anabaena* sp. PCC 7120 (Alam et al., 1986) and *Synechococcus* sp. PCC 7942 (Reith et al., 1986), and the *cpe*A gene encoding the α subunit of phycoerythrin in *Calothrix* sp. PCC 7601 (Mazel et al., 1986). By using two independent oligonucleotide mixtures, it is possible to minimize false-positive signals normally obtained in such experiments. Success in such experiment requires careful planning of the cloning procedure, fine tuning of the hybridization conditions, empirical determination of stringency to allow hybridization of only a perfect match sequence, and use of independent probe mixtures for a particular sequence. The third strategy utilizes unique-sequence oligonucleotide probes 30–50 base pairs in length. Codon usage data are used to predict the most likely base to be at a degenerate position, and deoxyinosine may be inserted at ambiguous codon positions (Takahashi et al., 1985). By careful selection of target sequences, the probes can be synthesized with approximately 75–80% resemblance, and hybridization may result in positive signals under restrictive conditions, as with heterologous probes. This strategy was successfully used to clone the *gvp*A gene of *Calothrix* sp. PCC 7601 (Tandeau de Marsac et al., 1985) and the *psb*E and *psb*F genes of *Synechocystis* sp. PCC 6803 (Pakrasi et al., 1988) and *Cyanophora paradoxa* (Cantrell and Bryant, 1987a).

This third method has now gained a strong momentum due to the development of the polymerase chain reaction technique (PCR), which simplifies a technically tedious protocol and makes it possible to isolate even rare sequences present at very low frequency within the largest genomes of organisms. This technique dimin-

ished concern for the region of a known polypeptide to be used to minimize the number of different oligonucleotide sequences in the synthesized mixture (due to the ambiguity of codon usage). The 5′-regions of the oligonucleotides can be designed to contain restriction sites for an easy cloning of the PCR product into a vector.

Immunological Screening

This method was developed for immunological screening of expression libraries containing the genes of interest from various sources. Antiserum is applied to the expressed gene product derived from the library and may signal the desired clone by immunological reaction followed by radiolabeled or colorimetric visualization. Since many cyanobacterial genes may be weakly expressed or not expressed at all from their own promoters in *Escherichia coli*, the screening may be facilitated by using expression vectors such as pUC plasmids (Vieira and Messing, 1982) or lambda phages (Young and Davies, 1983). This immunological approach was employed successfully in the isolation of clones encoding the *cpc*B gene of *Cyanophora paradoxa* (Lemaux and Grossman, 1983), the linker phycobiliprotein of *Nostoc* sp. PCC 8009 (Zilinskas and Howell, 1987), and the 35-kDa extrinsic protein of the oxygen evolution complex (OEC) of PS-II from *Synechocystis* sp. PCC 6803 (Philbrick and Zilinskas, 1988). In the latter case, antiserum raised against the spinach 33-kDa extrinsic protein of OEC cross-reacted with cyanobacterial the polypeptide.

This technique demonstrates the structural similarity between components of the photosynthetic apparatus of cyanobacteria and higher plants. The alpha, beta, and gamma subunits of the ATPase synthase are closely related to their plant homologs, as indicated by immunodecoration (Hicks et al., 1986). This similarity was confirmed by nucleotide sequence analysis of the corresponding genes from *Synechococcus* sp. PCC 6301 (Cozens and Walker, 1987) and *Anabaena* sp. PCC 7120 (Curtis, 1987). Similar results were obtained for components of both photosystems, the plastoquinol-plastocyanin reductase, and other enzymatic and soluble electron-transfer proteins (Vermaas et al., 1986; Nechushtai et al., 1983; Van der Vies et al., 1986).

RNA-DNA Hybridizations

This approach can use as probes only conserved genes and stable RNA molecules. Ribosomal RNAs (rRNA) are stable molecules and are widely used for determination of evolutionary development or relationships between various organisms. Chloroplast rRNA probes were suc-

cessfully used to clone the rRNA genes (*rrn*) of *Synechococcus* sp. PCC 6301 (*Anacystis nidulans*) (Tomioka et al., 1981; Tomioka and Sugiura, 1983, 1984; Kumano et al., 1983; Douglas and Doolittle, 1984a, 1984b). In this study it was discovered that the tRNA and rRNA primary and secondary structures of *Synechococcus* sp. PCC 6301 bear closer resemblance to those of chloroplast RNAs than to their counterparts in *Escherichia coli*. These similarities strengthen the endosymbiotic hypothesis, implying that eukaryotic chloroplasts are derived from an ancestral photosynthetic prokaryote (Gray and Doolittle, 1982). In addition, 14 out of 15 nucleotides at the 3′-end of the 16S rRNA are identical in *Escherichia coli*, *Synechococcus* sp. PCC 6301, and tobacco chloroplasts. Hence, it is very likely that transcripts in these three phylogenetic variable organisms have the same ribosome binding sites (Tandeau de Marsac and Houmard, 1987).

Regulation of Gene Expression

Promoter Sequences, Codon Usage, and Ribosome Binding Sites

From the cyanobacterial promoter regions elucidated so far, some homology between Pribnow boxes in *E. coli* and cyanobacteria was observed. This suggests common characteristics of RNA polymerase binding sites in both organisms. This assumption is supported by the fact that several prokaryotic genes such as *cat, lac*Z, *npt,* and *lux* are well expressed in cyanobacteria. The major variation in the Pribnow consensus is at the −35 region (Reith et al., 1986). This may be partly explained by the fact that regulation of the expression of some cyanobacterial genes involves complex processes and mechanisms like chromatic adaptation and heterocyst differentiation that may be under developmental and/or environmental regulation.

Codon usage in cyanobacteria can be evaluated by comparing the nucleotide sequence to that of the amino acid product (Shinozaki et al., 1983). Such a survey showed that codon usage is variable between unicellular and filamentous strains; correlation between the GC content in cyanobacterial DNA and the utilization of GC-enriched codons is maintained, particularly in *Synechococcus* PCC 6301; on a quantitative basis, the codon usage in cyanobacteria and *E. coli* is compatible, with the exceptions of the codons for leucine and proline.

From comparisons between the ribosome binding region in *E. coli* and the sequence of the 16S RNA of *Synechococcus* PCC 6301, some complementary sequences were identified. Also,

the binding and activity of cyanobacterial ribosomes are affected by specific inhibitors of prokaryotic ribosomal functioning. Still, in other instances, the eukaryotic-like initiation via scanning of cyanobacterial ribosomal functioning is also encountered. Thus, the mechanism used for the initiation of translation in cyanobacteria still remains an open question.

Regulation of Cyanobacterial Gene Expression

Promoter sequences and DNA binding factors have been looked at in order to understand gene regulation in cyanobacteria. Most of the genes under study belong to the major complexes related to light harvesting, photosynthesis, and nitrogen fixation, but genes involved with ATP formation and cell differentiation have also been investigated. Haselkorn and coworkers cloned the genes for a putative sigma factor and for the gamma subunit of RNA polymerase from vegetative cells of *Anabaena* PCC 7120. Both genes possess homology to their *E. coli* counterparts. Study of their inactivation may provide insights into the regulation of transcription in this cyanobacterium. The RNA polymerase of *Anabaena* PCC 7120 contains five different subunits: an α subunit that is related to an *E. coli* counterpart; a β subunit that contains the nucleotide binding site and is strongly related to the *E. coli* subunit; a β′ subunit that is weakly related to the β′ subunit of *E. coli*; a 66-kDa polypeptide that is related to the β′ subunit of *E. coli*; and a 52-kDa polypeptide that is related to another *E. coli* subunit. More than 10 cyanobacterial species were tested and found to contain a unique subunit of RNA polymerase that is not found in all other eubacteria; this places them, as a group, closer to archaebacteria (Haselkorn et al., 1983).

As mentioned in "Chromatic Adaptation," the synthesis of phycobiliproteins is regulated by light quality. Similarly, the synthesis of some of the linker polypeptides that are noncolored proteins required for assembly of phycobilisomes, depends on the light spectrum. Color mutants induced by UV mutagenesis in *Synechocystis* PCC 6701 were analyzed by Anderson and coworkers (1984). Characterization of rod and core assembly intermediates accumulating in such mutants enabled specific models to be proposed for both the assembly pathway and the final structure of the phycobilisomes in this cyanobacterium. From the various analyses performed so far with *Fremyella*, *Cyanophora*, *Agmenellum*, and *Synechocystis*, it is clear that sets of genes encoding phycobiliproteins that are polycistronically transcribed exist in cyanobacteria. The response of the various genes to alterations in light quality represents another regulatory mechanism. However, the DNA sequences involved in turning on/off the transcription of a certain gene or the binding of secondary affectors like DNA-binding proteins that inhibit/enhance expression, are still unknown.

Nitrogen fixation has been studied extensively in *Anabaena* PCC 7120 (Haselkorn, 1986). The arrangement of the genes encoding the protein components of the nitrogenase complex in *Anabaena* is different from that found in *Klebsiella*, *Azotobacter*, and *Rhodopseudomonas*. In the latter bacteria, *nif* H, *nif* D, and *nif* K encoding dinitrogenase reductase and dinitrogenase α and β subunits, respectively, are contiguous and cotranscribed from a promoter next to *nif* H. The same gene organization is observed in *Anabaena* vegetative cell DNA, except that there is just over 11 kb of DNA between *nif* D and *nif* K. Most of this DNA is not transcribed either in cells growing on ammonia or induced for nitrogenase formation. Golden et al. (1985a, 1985b) have elucidated a unique process of DNA excision during heterocyst differentiation in *Anabaena*. An 11-kb DNA fragment between *nif* K and *nif* D that contains the *xis*A gene is excised, followed by recombination between directly repeated, identical 11-bp sequences located within the coding regions of both genes. A consequence of the excision is that the ORF of *nif* D is fused to the 5′-flanking sequence of *nif* K, thus replacing 26 amino acids by 43 different amino acids. The polycistronic transcript produced by the new operon is 5 kb long and contains sequences for all three *nif* genes.

Another rearrangement occurring during *Anabaena* heterocyst formation involves the *nif* S gene, which is required for nitrogenase maturation. A DNA region adjacent to *nif* S gene (located 3′ to *nif* H in *Anabaena* vegetative-cell DNA) is rearranged via a site-specific recombination. Interestingly, the sequences at the junctions involved in the recombination differ from the sequences at the recombination junctions of *nif* D. It is suggested that two different recombination enzymes are involved in the two rearrangements.

A number of cloned genes that are turned on or off during heterocyst differentiation in *Anabaena* were used to demonstrate that the corresponding protein levels are regulated at the transcriptional level (Haselkorn et al., 1983; Wealand et al., 1989).

Machray et al. (1988) discovered an entire transposable element, IS2, near the *rbc* genes of the heterocystous cyanobacterium *Chloroglo-eopsis fritschii* CCAP1411/1b. This finding provides evidence of genetic transfer between the Gram-negative *E. coli* and cyanobacteria and may have significance in nucleotide sequence

rearrangements known to occur adjacent to the *rbc* and *nif* genes in some nitrogen-fixing cyanobacteria.

Gene Families

Gene inactivation is a useful tool for assessing the function of individual genes of a multigene family. This method was used to engineer a variety of cyanobacterial strains in which the functionality of members of gene families was analyzed. *Synechococcus* sp. PCC 7942 was examined for its three *psb*A genes by constructing mutants in which one or two out of the three genes were inactivated by an antibiotic-resistance cassette (Golden et al., 1986). This demonstrated that all three *psb*A genes are functional and that each is capable of producing sufficient Q_B protein to support the function of PS-II and photoautotrophic growth.

Golden et al. (1986) reported that out of the three members of this gene family, two functional forms of the Q_B protein are detected. Form I, produced by *psb*AI, differs by 25 residues from form II originating from *psb*AII and *psb*AIII, mostly in the amino terminus of the protein. By constructing translational gene fusions between the individual *psb*A genes and a *lac*Z gene from *Escherichia coli*, the expression of each of the *psb*A members could be followed in vivo under various illumination conditions. This experiment indicated a differential expression of the *psb*A gene family dependent on the light availability. Expression of *psb*AI is 500-fold and 50-fold greater than expression of *psb*AII and *psb*AIII, respectively, under similar illumination. If light intensity was decreased there was increased expression of the *psb*AI reporter and decreased expression of the other two genes. These results are supported by earlier reports on the relative abundance of the *psb*A transcripts in this organism when probed with antisense RNA from upstream untranslated regions of the three genes (Brusslan and Haselkorn, 1989).

Analysis of the putative promoter regions of the three *psb*A genes indicated an *E. coli*-like consensus sequence preceding the *psb*AII and *psb*AIII coding regions, whereas the *psb*AI putative promoter lacks a conserved −10 sequence (Golden et al., 1986). This difference is strengthened by the finding that the *psb*AI-*lac*Z fusion that is highly expressed in the cyanobacterium failed to produce the blue colony phenotype in *E. coli* plated in presence of the β-galactosidase indicator 5-bromo-4-chloro-3-indolyl β-D-galactopyranoside (X-Gal).

These observations indicate that some cyanobacterial promoters are regulated differently than *E. coli*-like promoters and that they can be enhanced by environmental factors like high light intensity. The mechanism involved in such regulation is still unknown.

The function of two *psb*D genes coding for the D2 protein of PS-II was similarly analyzed. Since *psb*DI and *psb*C genes overlap, an additional *psb*C gene was inserted into the *psb*DII locus, thus creating a strain in which *psb*DI alone could be inactivated. This experiment demonstrated that, although not essential for viability, expression from the *psb*DI locus is required for optimal growth (Golden et al., 1989) while *psb*DII is dispensable under laboratory growth conditions.

Expression of Cyanobacterial Genes in *Escherichia coli*

A number of cyanobacterial genes were cloned, and in some instances expressed, in *E. coli* (Gurevitz et al., 1985; Gatenby et al., 1985). In most of these experiments, the genes were placed under an *E. coli* promoter to ensure binding of RNA polymerase. However, the phosphatase gene from the nitrogen-fixing cyanobacterium *Nostoc commune* UTEX 584 was cloned and was most probably expressed from its own promoter in *E. coli* (Xie et al., 1989).

Chromatic Adaptation

The response of photosynthetic organisms to light has been a major issue in photosynthesis research. The correlation between the ability to sense and capture light to many outcoming processes, including the onset of gene expression, biochemical and metabolic pathways, and the synthesis and assembly of building blocks for specific subcellular structures, was studied extensively. Cyanobacteria have developed a unique mechanism for optimizing their light-harvesting potential when exposed to changes in the spectral quality of light. This is achieved by adjusting their photosynthetic pigment system via an increase or decrease of the constituents of the photosynthetic apparatus and an adaptive rearrangement of various components involved in light capture and its transformation into biochemical energy (Post et al., 1989). Variations in the ambient light regime are reflected in various adaptation features existing in many eukaryotic algae and prokaryotic photosynthesizers. Yet, cyanobacteria are unique in that they possess phycobilisomes with which they are able to adjust their light-harvesting potential by changing the molar ratio of the phycobilins, the pigmented proteins within the phycobilisomes. This process was termed "complementary chromatic adaptation" by Bennet and Bogorad (1973) and Tandeau de Marsac (1977). It involves a complete turnover of the phycobilisome structure,

and its genetic control is currently under extensive study by cyanobacterial molecular biologists. An understanding of phycobilin synthesis will allow the recognition of genes involved in a regulatory mechanism representative of those involved in adaptation to environmental variations.

The cyanobacterium *Calothrix* sp. PCC 7601 (*Fremyella diplosiphon*) was the focus for the studies related to the chromatic adaptation. Conley et al. (1986) elucidated the genes for the synthesis of the phycobiliproteins. Three sets of the alpha and beta allophycocyanin (APC) genes, plus two sets of the alpha and beta phycocyanin (PC) genes, are all transcribed off the same strand of a 13-kb cluster on the cyanobacterial genome. The order of their arrangement seems to be conserved, as was previously found in the cyanelle DNA of the eukaryotic alga *Cyanophora paradoxa* (Lemaux et al., 1983, 1985). Pilot and Fox (1984) isolated the phycobiliprotein genes from *Agmenellum quadruplicatum* by using oligodeoxynucleotide probes based on the amino acid sequence of PC of *Agmenellum*. They succeeded in isolating the gene cluster of these proteins, determined their order to be PCβ, PCα, and found that these genes are cotranscribed in white light from an *E. coli*-like promoter. Similar results were obtained by (De Lorimier et al. (1984), who used a replicating plasmid to introduce the cloned genes APCα and β from *Cyanophora* into *Agmenellum*. The phycobilisomes were purified from the recombinant organism (De Lorimier et al., 1987), and isoelectric focusing of the phycobiliproteins permitted discrimination between *Agmenellum* and *Cyanophora* APC. Some *Cyanophora* APC could be detected in assembled bilisomes, indicating that bilin attachment to apoprotein and correct assembly into bilisome cores is possible in a heterologous host. Such an experiment paves the way for an in vitro mutagenesis program for the study of assembly and structure/function relationships of these proteins.

Differentiation

Formation of heterocysts in some filamentous cyanobacterial strains provides an excellent system for studying cell differentiation. The heterocysts are physiologically, biochemically, and structurally distinct from the vegetative cells. They can express genes that are inactive in the vegetative cells, and synthesize constituents for new metabolic pathways functioning in the assimilation of molecular nitrogen. Concomitantly, these specialized cells lose their photosynthetic capacity (structures and function) and become the nitrogen suppliers of the filament. It

should be extremely interesting to probe with a molecular marker the early detection of genes which turn on before any obvious changes are observed.

For genetic analysis of filamentous cyanobacteria, Schmetterer et al. (1986) constructed mobilizable plasmid vectors able to express the luciferase gene in *Anabaena* species. These *lux* genes may be utilized as promoter probes for studies of cell differentiation in the filaments. Indeed, this approach was recently rewarded when Holland et al. (1989) followed the induction of the *het*A gene in the premature heterocysts of *Anabaena* PCC 7120. Wolk and Elhai (personal communication) developed a remarkable technology in which transcriptional fusions put the expression of luciferase under the control of *het*A transcriptional signals. Light emitted by individual cells within filaments could be monitored by an image processing system attached to a conventional microscope. In this experiment, 9 h after nitrogen deprivation, cells emitting light were observed at intervals along the cyanobacterial filament. Only later, these cells became structurally distinguishable from the rest of the vegetative cells. It was concluded that *het*A is a gene that is expressed early in the differentiating filament of *Anabaena*. This approach provides a breakthrough in the understanding of the biochemical and genetic control of heterocysts differentiation in nitrogen-fixing cyanobacteria and may be used in the characterization of developmentally impaired mutants (Wolk et al., 1988).

Metabolism

Photosynthetic Genes

Cyanobacteria appear to be ideal organisms for the genetic study of photosynthesis since they perform photosynthesis similar to that of higher plants (Ho and Krogmann, 1982), and some species are available for genetic manipulations (Williams, 1988). However, most of the cyanobacterial strains studied are obligate autotrophs, and therefore most mutations in genes involved in photosynthesis are lethal. This problem may be overcome in two ways: 1) by the isolation of conditional lethal mutations; or 2) by the use of a facultatively heterotrophic strains which are capable of growing on an exogenous source of organic carbon (Rippka, 1972). Pakrasi et al. (1988) developed a genetic technique for molecular analysis of electron transport in PS-II in *Synechocystis* PCC 6803. Their methodology involves deletion of specific genes from the cyanobacterial genome and replacement with mutant genes prepared by site-directed

mutagenesis. In this way it is possible to investigate the role of specific amino acid residues of a given polypeptide involved in binding pigments or the role of various cofactors in the overall activity of this complex. Two important characteristics of *Synechocystis* strain PCC 6803 permit such studies: 1) their naturally occurring genetic transformation system (Grigorieva and Shestakov, 1982); and 2) their ability to grow photoheterotrophically on glucose, which is necessary for the propagation of PS-II mutants that are incapable of photosynthesis (Rippka, 1972; Jansson et al., 1987). This strain was recently used in an elegant molecular experiment aimed at the elucidation of the identity of Z, the primary electron donor to the PS-II reaction center, and D, an oxidizable PS-II component structurally resembling Z. For many years, Z and D were assumed to be plastoquinols based on a variety of physical measurements performed on the oxidized donors. However, since tyrosine radicals may yield similar physical signals to those seen in PS-II, the strongly conserved tyrosine 160 in the D2 polypeptide adjacent to the reactive histidine residue associated with P680-binding was changed to a phenylalanine (Debus et al., 1988; reference is not an exact matchVermaas et al., 1988) by site-directed mutagenesis. This change resulted in the disappearance of the electron paramagnetic response signal and led to the conclusion that tyrosine 160 in the D2 protein is the electron donor D and, by analogy, tyrosine 161 in the D1 polypeptide is electron donor Z. This discovery was achieved by site-directed modification in a cloned *psb*D gene, followed by its introduction back into the cyanobacterial genome of *Synechocystis* PCC 6803. In a different study, Pakrasi et al. (1988) examined the role of the *psb*E, *psb*F, *psb*I, and *psb*J gene products in PS-II of *Synechocystis* PCC 6803. They used site-directed mutagenesis of cloned ORFs of the *psb*EFIJ operon and demonstrated a complete loss of PS-II assembly and activity when the entire operon was deleted.

Sugar Metabolism

The primary pathway for the catabolism of endogenous glucose in cyanobacteria is the oxidative pentose phosphate cycle. This pathway is important for maintaining ATP and reducing power levels during darkness. In addition, in nitrogen-fixing cyanobacteria, this cycle may contribute reducing power for nitrogenase activity. The levels of glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase are sevenfold higher in heterocysts than in vegetative cells, suggesting that there is a genetic control of these enzymes in cyanobacteria which is linked to environmental effects on sugar metabolism. During the transition of a *Synechococcus* PCC 7942 culture from exponential growth to stationary phase, an increase in the specific activity of the enzyme 6-phosphogluconate dehydrogenase (6PGD) is observed. By fusing the *gnd* gene with a promoterless *lacZ* gene and transforming a *gnd⁻ Synechococcus* mutant, the growth-phase-dependent induction of 6PGD synthesis was found to be regulated at the transcriptional level. Although cyanobacteria are known to assimilate inorganic carbon via the C-3 reductive photosynthetic pathway, they also fix large amounts of carbon in the light as C-4 acids. Malate and aspartate are the major products of phosphoenolpyruvate carboxylase (PEPCase) activity. It is possible that PEPCase activity replenishes the TCA cycle with intermediates that are used for biosynthetic purposes. A genetic approach to determine the role of the enzyme in cyanobacteria may confirm this assumption. Such an experiment should involve the isolation of the *ppc* gene, followed by insertional inactivation that will indicate whether this gene is dispensable.

RUBISCO The study of rubisco structure and function was for many years an attractive challenge due to its central role in photosynthesis and CO_2 fixation. Some of the progress gained recently has been achieved by a molecular genetic approach that involves *rbc* genes derived from cyanobacteria. Since the large subunit of the enzyme is coded in higher plants by the chloroplast genome, and chloroplasts are still untransformable, it is impossible to genetically modify the large subunit of the enzyme (*rbc*L) in higher plants. Attempts to express the holoenzyme in vitro by introducing the *rbc*L and the *rbc*S genes in various ways into *E. coli* were unsuccessful. The *rbc* gene from the photosynthetic anaerobe *Rhodospirillum rubrum* has been expressed in *E. coli* and various mutations have been introduced, but the *R. rubrum* enzyme is quite different from the enzyme of higher plants. On the other hand, cyanobacteria possess a rubisco enzyme very homologous to that of higher plants, which has the substantial advantage of carrying both *rbc* genes on a single operon. This feature permitted the successful expression of rubisco from a variety of cyanobacteria in *E. coli* (Gatenby et al., 1985; Gurevitz et al., 1985; Tabita, 1988). Although many technical difficulties still limit the development of a reliable selection system to study structure/function relationships of rubisco, it may perhaps be easier to approach in transformable cyanobacteria. Meanwhile, polypeptidic chaperonins (factors assumed to play a role in the assembly of rubisco) were proposed and their involvement demonstrated by using expression vectors con-

taining *rbc* genes from *Synechococcus* PCC 6301 (Goloubinoff et al., 1989).

C_I P_UMP In cyanobacteria, the dependence of photosynthesis on external inorganic carbon is regulated by the presence of an inducible active inorganic carbon (Ci) transport system. This system operates to elevate the intracellular concentration of CO_2 so that the relatively low-affinity cyanobacterial rubisco may function at an efficiency close to that occurring at CO_2 saturation levels. Four key operational elements have been defined for this concentrating mechanism: 1) a transport system; 2) a means to energize the transport by photosynthesis; 3) a leak barrier to reduce the back flux of CO_2; and 4) a mechanism to rapidly interconvert inorganic carbon species within the cell (Reinhold et al., 1987). Interconversion of inorganic carbon species is necessary so that CO_2, the substrate required by rubisco, is formed from HCO_3^-, the carbon species that is delivered to the cell. Recently, a molecular approach to resolve the mechanism of this interconversion was initiated by several groups trying to resolve the various constituents of the concentrating mechanism. The strategy employed is the creation of mutants requiring high levels of CO_2 and using these mutants in genetic complementation experiments aimed at identifying components and genes of the system. Price and Badger (1989) succeeded in expressing a carbonic anhydrase derived from human tissues in the cytosol of *Synechococcus* PCC 7942 and created a high-CO_2 requirer. This was probably due to the conversion of cytosolic HCO_3^- into CO_2, which leaked out from the cell and prevented the accumulation of HCO_3^- within the carboxysomes. This loss of the ability to accumulate internal Ci confirmed the previous assumption that the carbonic anhydrase enzyme resided only within the carboxysome. Ogawa et al. (1987) isolated a high-CO_2 requirer (RK1) from *Synechococcus* PCC 7942, pinpointing a 42-kDa protein not synthesized in the mutant and obtained such a mutant (RKb) with *Synechocystis* PCC 6803 (J. Pierce, personal communication). Kaplan and co-workers isolated the E1 and 0221 mutants of *Synechococcus* PCC 7942, which require elevated CO_2 levels for growth. Recently, they oriented DNA sequences relative to the *rbc* locus, which seem to play a role in carboxysome formation, thus indirectly creating a requirement for higher CO_2 concentration (Friedberg et al., 1989).

Stress

Adaptation of cyanobacteria to stress conditions has been documented in several instances. *Microcystis firma*, like most other cyanobacteria, is unable to adapt to higher salt concentrations in the dark but in response to salt stress in the light, an osmoregulant, glucosylglycerol, found thus far only in cyanobacteria, is synthesized from glycogen. When the glycogen pool is depleted in the dark, glucosylglycerol is not produced in sufficient amounts. In the light, the salt-dependent accumulation of glucosylglycerol is characterized by negligible turnover in salt-adapted cells and by small but continuous leakage of this substance into the medium (Hagemann et al., 1987).

Iron is an essential component of photosynthetic cytochromes and of nonheme iron-sulfur proteins. In photosynthetic organisms, ferredoxin functions primarily as the terminal electron acceptor of the photosynthetic electron transport chain. Under conditions of moderate iron limitation, the Fe-S protein ferredoxin is replaced by the flavoprotein flavodoxin. The genes encoding ferredoxin and flavodoxin proteins were cloned from *Synechococcus* PCC 7942. Whereas the gene encoding ferredoxin is constitutively transcribed, flavodoxin was found to be transcriptionally regulated by the availability of iron. The flavodoxin mRNA was observed only in a medium low in iron, and it disappeared upon addition of iron (Laudenbach et al., 1988).

Phycocyanins represent approximately 35% of the total cell protein of *Calothrix* sp. PCC 7601. Three phycocyanin operons were characterized in this cyanobacterium by Tandeau de Marsac et al. (1988). Regulation of the third operon, *cpc*3, represents a novel response to environmental stress. The expression of the *cpc*3 operon is turned on under sulfur limitation, while *cpc*1 and *cpc*2 are switched off. The protein product of this operon lacks sulfur-containing amino acids except for those at chromophore-binding sites. This adaptation allows survival of the cell under extreme growth conditions represented by sulfur limitation (Tandeau de Marsac et al., 1988).

The availability and turnover of phosphorus may play a key role in determining the development of water blooms or of economically important nitrogen-fixing communities such as those found in rice fields. The gene *iph* (for indole phosphate hydrolase) may be useful for the study of phosphate regulation in cyanobacteria and may prove useful in the study of cyanobacterial promoter function, a subject on which there are limited data (Schneider et al., 1987).

A new UV-A/B-absorbing pigment bound to a polysaccharide core which had maxima at 312 and 330 nm was found in the cosmopolitan terrestrial cyanobacterium *Nostoc commune*. The pigment is found in high amounts (up to 10% of

dry weight) in colonies grown under solar UV radiation but only in low concentrations in laboratory cultures illuminated by artificial light without UV. Synthesis of the pigment is induced by UV light, and the pigment protects *Nostoc* from UV radiation. *Nostoc* is also capable of withstanding extreme water stress (drought). Apparently, the UV pigment can participate in water storage, since it is a polysaccharide and is located outside the cell in the polysaccharide matrix (Scherer et al., 1988).

Biotechnology

There is increasing interest in the use of cyanobacteria for biotechnology for two main reasons: 1) Because of the great similarity of their photosynthetic apparatus to that of higher plants, cyanobacteria are excellent model systems for studying oxygenic photosynthesis. 2) Mass cultivation of cyanobacteria has become a promising route for the production of large quantities of natural products of biotechnological and agricultural values.

Model Systems

Resistance to herbicides of the triazine and urea types in higher plants is a chloroplastic trait. Such resistance is a single-gene trait and may be utilized in the future for genetic engineering of crop plants. However, no reliable procedure for stable transformation of chloroplasts is available. Assuming that such a procedure will become feasible, it is necessary to better understand the phenotypic expression of the triazine-resistance gene. Thus, identical and diverse mutations have been introduced into the *psb*A gene encoding the D1 protein in the cyanobacterium *Synechococcus* PCC 7942. This reaction center II polypeptide was found to be the primary site for mutations conferring triazine resistance. The power of cyanobacterial molecular genetics was employed in the introduction of a variety of mutations to enable the elucidation of the D1 architecture in the thylakoid membranes, and the construction of a *Synechococcus* PCC 7942 strain that is partially diploid for *psb*A and heterozygous for triazine resistance (Pecker et al., 1987). From this experiment it was concluded that triazine resistance is a recessive trait in cyanobacteria. On the other hand, diuron resistance in *Synechococcus* PCC 7942 was reported to be a dominant trait by Brusslan and Haselkorn (1989).

Another important facet of future uses for cyanobacterial biotechnology may be related to rubisco. This key enzyme of CO_2 fixation controls the rate of net photosynthesis. Its complex structure and assembly, and the involvement of various factors in holoenzyme synthesis make it an extremely difficult target for genetic modification in higher plants. The simpler pathway of expression of a very similar enzyme in cyanobacteria makes it accessible to genetic manipulations which may lead in the future to better understanding of the relations between its structure and its kinetic properties.

Applications

FOOD AND NATURAL PRODUCTS. The possibility that mass cultures of specific cyanobacterial strains may be suitable for human or animal feeding is not new. The filamentous nonheterocystous cyanobacterium *Spirulina* has been part of some human diets in Africa for centuries, providing a rich source of protein, vitamins (particularly B_{12}), and the essential fatty acid gamma-linoleic acid (Cohen et al., 1987). This cyanobacterium can be grown on marginal land using saline water unsuitable for conventional agriculture. The filamentous nature of the cyanobacterium permits simple harvesting by filtration through screens. To make *Spirulina* a major food or animal feed product, its cost of production should be reduced while it is grown efficiently on a large scale. However, molecular genetics of *Spirulina* has not yet developed due to the lack of systems for transformation, transfection, or conjugation.

Cyanobacteria may be utilized for water treatment functions not practical by current mechanical or chemical means, such as purification via the incorporation of heavy metal ions.

Cyanobacteria grown on a large scale could be utilized for the production of various natural products such as polysaccharides, carotenoids, antioxidants, antibiotics, and precursors of pharmaceuticals.

Insect Control

The larvicidal gene of *Bacillus sphaericus* has been cloned and introduced into *Synechococcus* PCC 7942 by an autonomously replicating vector (Tandeau de Marsac et al., 1987). The recombinant cells produced active toxin whose level of activity against *Culex* mosquito larvae was found to be the same either in *E. coli* or in the cyanobacterium. Very often spores of *B. sphaericus* settle rapidly onto bottom mud and are removed from the larval feeding area. Introduction of such a cloned toxin into cyanobacteria, which grow on the upper layers of aquatic habitats, may provide an elegant solution for mosquito control, since cyanobacteria will persist longer in such an environment and reach target insect larvae more effectively than the spores do.

CHAPTER 2.3

The Genus *Prochlorococcus*

ANTON F. POST

General

Until the mid-1970s the general belief was that oxygenic photosynthesis among prokaryotes was limited to the cyanobacteria with their pigment complement of chlorophyll *a* and phycobiliproteins. This concept came under fire with the subsequent discoveries of the three so-called "prochlorophytes" *Prochloron didemnii* (Lewin, 1975a; Lewin and Withers, 1975b), *Prochlorothrix hollandica* (Burger-Wiersma et al., 1989) and *Prochlorococcus marinus* (Chisolm et al., 1988), which all lack phycobilisomes but possess chlorophyll *b* as a light harvesting pigment. An additional discovery of *Acaryochloris marina* (Miyashita et al., 1996), which contains chlorophyll *d* as the main pigment, increased appreciation for the plasticity of the photosynthetic pigment-complements of prokaryotes. The photosynthetic apparatus of the above-listed species and that of its cyanobacterial counterpart differed with respect to the genes encoding the light harvesting antenna proteins, the localization of these proteins, and the regulation of photosynthetic activities (Post and Bullerjahn, 1994; LaRoche et al., 1996; Bibby et al., 2003). However, phylogenetic studies unequivocally placed them within the cyanobacterial clade (Morden and Golden, 1989; Urbach et al., 1992). Moreover, later studies have shown that these different photosynthetic machineries are to a large extent different phenotypes of a common gene pool (see below). This then suggests that broad plasticity of photosynthesis is an exclusive property of the cyanobacteria, but that the name may not provide appropriate cover for this group of fascinating organisms. At present, *Prochlorococcus* is the best-characterized organism among the "atypically pigmented" cyanobacteria, and detailed information is available on natural populations, ecological physiology, photosynthesis, nutrient acquisition, genetics and genomics. *Prochlorococcus* spp. with a cell diameter of 0.6–1.0 μm is the smallest photosynthetic organism known to date. Cells are slightly ellipsoid and have typical Gram-negative bacterial structure with a cell envelope consisting of an outer membrane, cell wall, periplasmic space and a cytoplasmic membrane. Except for photosynthetic membranes, intracellular bodies are not seen. The thylakoids are slightly appressed but as in other cyanobacteria (and in contrast to algal and higher plant chloroplasts)—the grana and stroma have no particular organization. A varying number of thylakoid membranes together form a horseshoe-shaped structure in thin-section electron microscopy pictures. Type strains are *Prochlorococcus marinus* (Chisholm et al. 1992) subsp. *pastoris* subsp. nov. strain PCC 9511 (available from the Pasteur Institute; Rippka et al., 2000) and *Prochlorococcus* strain CCMP 1378 (available from the Bigelow Marine Laboratories; Garczarek et al., 1998). *Prochlorococcus* has further proven to be an excellent tool for the study of genetic diversity and niche adaptation of microbial populations in the open ocean. At the moment *Prochlorococcus* is an organism that continues to raise great interest in disciplines as varied as comparative and functional genomics, microbiology of cyanobacteria, biological oceanography, and biodiversity. Because of its global abundance, *Prochlorococcus* is also central to studies that focus on climate change, global warming, and carbon sequestration in the surface ocean.

Habitats

First hints of the existence of *Prochlorococcus* were obtained from electron micrographs (Johnson and Sieburth, 1979) and from apparently aberrant chlorophyll signatures in pigment high pressure liquid chromatography (HPLC) analyses of tropical Atlantic Ocean samples (Gieskes and Kraay, 1983; Gieskes and Kraay, 1986; Gieskes et al., 1988). These signatures were later shown to derive from the *Prochlorococcus*-specific divinyl chlorophylls *a* and *b*. *Prochlorococcus* populations were first detected when flow cytometry was employed on board oceanographic cruises, and culture isolates confirmed the flow cytometry signatures. At present this prokaryote is known as both the smallest and

most abundant photosynthetic organism in aquatic and terrestrial ecosystems. It has been estimated to contribute 10–20% of global primary productivity. The global distribution of *Prochlorococcus* is limited with much lower abundances at more temperate latitudes (<43°S and >43°N). Although the restriction of global distribution was thought to be due to a requirement for temperatures of 18°C and above, early work showed that *Prochlorococcus* still grows at 13°C (Moore et al., 1995). Populations are much reduced in waters over the continental shelves. However, the occurrence of *Prochlorococcus* has been reported for certain coastal waters (Yahel et al., 1998; Suzuki et al., 2000). Moreover, physical forcing of subtropical and tropical water bodies into deep mixing events works to reduce *Prochlorococcus* abundances (Olson et al., 1990; Lindell and Post, 1995; Durand et al., 2001), in certain cases even rendering them as insignificant populations (Lindell and Post, 1995). Three distinct types are recognized, mostly based on their pigmentation, photosynthesis and phylogenetic properties. Cells that have low chlorophyll contents, a low chlorophyll *b/a* ratio (<0.3), and a range of relatively high irradiances for growth and photosynthesis belong to the high light (HL) adapted ecotypes (Moore et al., 1998; Moore and Chisolm, 1999). Two such ecotypes (HLI and HL2) are distinguished phylogenetically (West and Scanlon, 1999). For reasons not yet understood, the HLI and HL2 ecotypes appear to be nearly mutually exclusive and they inhabit different ocean provinces (West et al., 2001; Rocap et al., 2002). The high light adapted ecotypes are found throughout the photic zone. Cells with a high chlorophyll content and a high chlorophyll *b/a* ratio (>0.3–3) belong to the low light adapted

(LL) ecotypes (Moore et al., 1998; Moore and Chisolm, 1999). Their divinyl chlorophyll *b* permits photon scavenging in the spectral range of 480–500 nm, the wavelengths which penetrate deepest below the ocean surface. It thereby allows the LL *Prochlorococcus* types to maintain actively dividing populations at depths where other photosynthetic organisms can hardly meet their energy requirements. Populations of LL ecotypes of *Prochlorococcus* are not found in the surface layers (<50 m depth). *Prochlorococcus* spp. have not been reported from freshwater or terrestrial ecosystems.

Strains

Besides the two classified type strains mentioned above, many different isolates, but few axenic, clonal cultures of *Prochlorococcus* have been obtained. Clonal cultures were obtained from isolates from many different sites (Table 1). Most *Prochlorococcus* isolates were collected and the resulting strains maintained by teams at the Department for Civil and Environmental Engineering at the Massachusetts Institute of Technology, Cambridge, Massachusetts, United States, and the Centre d'Etudes d'Océanologie et de Biologie Marine, Station Biologique in Roscoff, France. A number of strains have been deposited at the Culture Collection of Marine Phytoplankton (CCMP) at Bigelow Marine Laboratories. The axenic strain MED4 is available as strain CCMP1378 from this collection. A second axenic strain with a genotype and phenotype similar to MED4 has been deposited in the Pasteur Culture Collection as strain PCC9511 (Rippka et al., 2000). A vast array of strains have

Table 1. Three basic seawater-based media used for the isolation and cultivation of *Prochlorococcus* spp.

K/10(−Cu)[a]		PRO2[b]		PRO99[b]	
Nutrient	Final conc.	Nutrient	Final conc.	Nutrient	Final conc.

[a]The K/10 (−Cu) medium was used for initial *Prochlorococcus* studies, and often this medium was Tyndallized or microwaved rather than sterilized by autoclaving (Chisholm et al., 1992).
[b]The PRO2 and PRO99 media were derived from the K/10 (Cu) medium. PRO99 is best suited for growing *Prochlorococcus* to relatively high biomass levels (Moore et al., 2002).

been collected from the northern Atlantic (e.g., strains NATL1[A] and NATL2[A]), tropical Atlantic (e.g., TATL1 and TATL2), Gulf Stream (e.g., strains MIT9311, MIT9312, MIT9313 and MIT9314), Sargasso Sea (e.g., strains SS120 [CCMP 1375], MIT9301, MIT9302, MIT9303 and MIT9401), equatorial Pacific (e.g., strains MIT9211, MIT9215, MIT9321, MIT9322 and MIT9515), south Pacific (e.g., strains MIT9107, MIT9116, MIT9123, MIT9201 and MIT9202), western Pacific (strain GP2), Arabian Sea (strain AS9601), Red Sea (strain RS810), and Mediterranean Sea (strain MED4). Coastal waters yielded strain SB from Sugura Bay and strain TAK9803-2 from the Takapoto atoll. These strains form part of the culture collection at the Station Biologique in Roscoff, France (F. Partensky, personal communication). More detailed information on *Prochlorococcus* strains, their origin, phylogenetic affiliation, physiological properties (such as pigment type and nutrient acquisition) can be found in Scanlan et al. (1996), West and Scanlan (1999), Moore et al. (1998), Moore et al. (2002), West et al. (2001), and Rocap et al. (2002). Three strains (MED4 [axenic], MIT9313 and SS120) have been submitted to full genome sequence analysis (Dufresne et al., 2003; Rocap et al., 2003). These strains show small genomes (~1.6–2.3 Mb) some of which appear to condense into an even smaller size. The various *Prochlorococcus* genomes show some surprising properties, which are discussed below, including a considerable variation in G+C content, the presence of phycoerythrin encoding genes, the presence of 1–7 gene homologs encoding the light harvesting antenna polypeptides, lack of nitrate utilization genes etc. These strain differences are so striking that one is forced to conclude that *Prochlorococcus* is a group of very closely related ribotypes with distinctly different genetic and physiological properties (see below). These properties most likely testify to the highly specialized nature of each genotype in its adaptation to a neatly defined ecological niche.

Isolation and Cultivation

The isolation and cultivation of *Prochlorococcus* is still a slightly "tricky" activity although many stumbling blocks have been removed, aided by an increased understanding of this group's ecological physiology. As an organism originating from pristine, oligotrophic environments, *Prochlorococcus* growth develops most successfully in a seawater-based medium enriched with both macro and micronutrients supplied in 10- to 1000-fold lower concentrations than in media for most other cyanobacteria. Isolations of the first

isolates SARG, MED, NATL1 and NATL2 were performed in CTPC and K/10-Cu based media (Chisholm et al., 1992), but later additional media, like PRO99, proved more effective in obtaining new isolates. A working protocol for the isolation of additional *Prochlorococcus* strains involves the following steps:

1) Ensure that seawater samples are maintained at temperatures close to ambient. Avoid both cooling and heating of samples, even by only a few degrees. 2) Protect seawater samples from exposure to high sunlight by using darkened tubing and darkened collection bottles (e.g., amber Teflon bottles). 3) Use "acid-cleaned" tubing, filtration systems, and culture glassware. 4) Filter 250 ml of seawater (without applying pressure or vacuum!) by letting the sample drip through two stacked, 0.6–1.2 μm polycarbonate filters mounted on an acid-clean Nuclepore or similar filter funnel and 1-liter acid-clean flask. 5) Add nutrients aseptically to half or full medium strength, mix gently. 6) Transfer enriched seawater (about 10 ml) to sterile, glass culture tubes (polystyrene tubes can be used at sea). And finally, 7) place tubes in light and temperature conditions that closely match the environmental conditions of the original water sample.

This protocol aims at excluding the faster developing cyanobacterium *Synechococcus* as well as picoeukaryotic algae. As some *Prochlorococcus* types are known to have a cell diameter similar to that *Synechococcus*, this procedure may bias isolation in favor of the smaller *Prochlorococcus* types. Most of the cultures should be free of contaminating phytoplankton but not of heterotrophic bacteria. Additional environmental conditions thought to provide *Prochlorococcus* with a competitive edge are the use of low light intensities and the use of blue screens to simulate the deep underwater light climate.

The apparent random success of isolation and subsequent growth and unexplained loss of cultures triggered the use modifications to the medium such as sterilization by Tyndallization rather than autoclaving, omission of certain trace elements, addition of selenium salts, omission of glassware usage, etc. (Chisholm et al., 1992). Furthermore, the filtration of seawater over a 0.2-μm polycarbonate filter or over a Whatman GF/F glass fiber filter before nutrient additions and autoclaving, is recommended. These modifications were in general found to improve success rates for individual researchers but without achieving across-the-board success. At present, many of the erratically behaving cultures have settled into a more stable and predictable routine. Many cultures can now be successfully maintained in the standard ASW medium (based

on artificial seawater and added nutrients) developed by Waterbury and Willey (1988). Moreover, the use of carefully acid-washed filtration systems for seawater, the preparation of media in Teflon or polystyrene bottles, and the use of acid washed glassware (pre-autoclaved with double distilled or "milli-Q" water) greatly stabilizes the cultivation.

Prochlorococcus spp. can further grow on solid media (e.g., PRO99 or ASW medium supplemented with good quality agar purified according to the method of Waterbury). Cells grow best when included in a 0.6–0.7% sloppy top agar prepared with medium containing 10% spent medium (v/v), i.e., culture liquid first centrifuged or gently filtered to remove the cells, passed through a sterile filter setup, and finally added to lukewarm medium-agar mix just before pouring.

Pigments and Photosynthesis

Chlorophylls

Chlorophylls *a* and *b* (the main photosynthetic pigments of *Prochlorococcus*; Chisholm et al., 1988) are found also in *Prochloron* and *Prochlorothrix* but rarely in other cyanobacteria. The dominant chlorophyll *a* and *b* species are of the divinyl-chlorophyll or 8-desethyl, 8-vinyl chlorophyll type, as opposed to the monovinyl chlorophylls found in all other known photosynthetic organisms (Chisolm et al., 1992; Goericke and Repeta, 1992). In retrospect, this characteristic, borne out by the different retention times of the two chlorophyll species in HPLC analyses, was the first hint of *Prochlorococcus*' existence in subtropical and tropical waters (Gieskes and Kraay, 1986). Divinyl chlorophyll *a* is the only chlorophyll *a* type encountered in *Prochlorococcus*, and this apparently includes the special pairs of chlorophyll *a* molecules located in the reaction centers of photosystem I and II (Goericke and Repeta, 1992). Some *Prochlorococcus*, including HL strains MIT9302, MIT9312 and LL strains MIT9211 and SS120, contain some monovinyl chlorophyll *b* next to divinyl chlorophyll *b* (Moore et al., 1995; Moore and Chisholm, 1999). Other *Prochlorococcus* have low levels of a chlorophyll *c*-like pigment, presumably Mg 3, 8 divinyl pheoporphyrin a$_5$ (Goericke and Repeta, 1992). Two ecotypes of *Prochlorococcus* are known: high light (HL)- and low light (LL)-adapted types, distinguished by their divinyl chlorophyll *a* and *b* contents. The LL *Prochlorococcus* have high divinyl chlorophyll *a* and *b* contents and high chlorophyll *b/a* ratios as compared to their HL counterparts. These types largely reflect the environment in which they thrive,

with most HL types having been isolated from well-illuminated surface layers and LL types originating from deeper layers near the bottom of the photic zone. Their pigment properties are retained by culture isolates (Moore et al., 1998; Moore and Chisholm, 1999) and relate to differences in photosynthetic antenna structure and the gene complements encoding the antenna proteins (Garczarek et al., 2000; Bibby et al., 2003).

Phycobiliproteins

Despite the early recognition that *Prochlorococcus*, *Prochloron* and *Prochlorothrix* belong to the cyanobacteria (Urbach et al., 1992), it was quietly assumed that their chlorophyll *a/b* antennae and the cyanobacterial phycobilisomes are mutually exclusive. The assumption has been put to the test with the discovery of orange fluorescence—typical of phycoerythrin—in *Prochlorococcus* samples from >100 m depth in the Pacific Ocean (Hess et al., 1996). Subsequently, the presence of the *cpeA* and *cpeB* genes encoding the α and β subunits of phycoerythrin were identified in *Prochlorococcus* CCMP1375 (= strain SS120; Hess et al., 1996). The genes are phylogenetically most closely related to phycoerythrin II genes of marine *Synechococcus*, but the genes of both the α- and β-subunits of *Prochlorococcus* phycoerythrin have stretches of high sequence dissimilarity (Hess et al., 1996). Moreover, the α-subunit of *Prochlorococcus* phycoerythrin contains only one chromophore binding site as opposed to 2–3 in marine *Synechococcus* (Hess et al., 1996). Hence this phycoerythrin was proposed to constitute a novel type named "phycoerythrin III," the main chromophore of which was identified as phycourobilin rather than phycoerythrobilin (Hess et al., 1996). A putative γ-linker polypeptide was identified for phycoerythrin III, suggesting that the phycoerythrin III subunits form a coherent functional complex (Hess and Partensky, 1999a). Phycoerythrin of *Prochlorococcus* CCMP 1375 was found in the thylakoid membranes, and its cellular levels were shown not to be affected by light intensity or growth phase (Hess et al., 1999b). Phycoerythrin is capable of light harvesting and excitation energy transfer to chlorophyll *a* (Lokstein et al., 1999). So far, phycocyanin and allophycocyanin (pigments required for energy transfer from phycoerythrin to photosystems in phycobilisome-containing cyanobacteria) have not been detected in *Prochlorococcus*. The genes encoding phycoerythrin III form a gene cluster, and their organization on the chromosome is similar to that found in marine *Synechococcus* (Hess et al., 1999b). This cluster is located at a locus <110 kb away from a gene cluster encoding photosyn-

thetic function. The two main light harvesting pigment systems in marine cyanobacteria have evolved, hypothetically, from a light harvesting antenna system of an ancestral cyanobacterium in iron-limited ocean environments (Ting et al., 2002).

Carotenoids

The carotenoid composition of *Prochlorococcus* also differs from that of other cyanobacteria. Typically, zeaxanthin, α-carotene and an additional so far unidentified carotenoid are found as the major carotenoids of *Prochlorococcus* (Chisholm et al., 1988; Goericke and Repeta, 1992). These pigments are not considered to have a light harvesting function. The cellular ratios of zeaxanthin to divinyl chlorophyll levels show dramatic change with changes in light intensity or light quality (Moore et al., 1995; Bricaud, 1999). These changes are mainly due to changes in chlorophyll contents of the cells. In contrast, α-carotene levels seem to change in concert with divinyl chlorophyll *a* in *Prochlorococcus* cultures adapted to high versus low light intensities (Moore et al., 1995). Still uncertain is how much of the zeaxanthin is associated with cell surface in *Prochlorococcus*. Much of the zeaxanthin in, e.g., *Prochlorothrix hollandica* accumulates at the cell surface and the synthesis is induced under high light conditions (Engle et al., 1991).

Pigment-Protein Complexes

Both Photosystem I (PSI) and divinyl chlorophyll *a/b*-protein (Pcb) complexes of *Prochlorococcus* CCMP 1375 (strain SS120) and CCMP 1378 (strain MED4) have been isolated and characterized (Partensky et al., 1997; Garczarek et al., 1998; Van der Staay et al., 1998). The characterization of PSI showed a high degree of similarity to PSI of other cyanobacteria. The core proteins PsaA and PsaB were identified immunologically in both strains on the basis of crossreaction with heterologous antibodies (Garczarek et al., 1998). The PsaL protein was shown to have a distinct N-terminus but to be otherwise very similar to other PsaL proteins (Van der Staay et al., 1998). *psaI* and *psaL* were identified as neighboring genes and found to be potentially cotranscribed (Van der Staay et al., 1998). PSI preparations show PSI is in the trimeric form, of which each monomer contains approximately 100 divinyl chlorophyll *a* and *b* molecules per P_{700} in both the MED4 and SS120 strains (Garczarek et al., 1998). Photosystem II (PSII) has not been characterized extensively, but electron microscopy established that PSII is

found mainly in the dimeric form (Bibby et al., 2003).

The truly unique feature of the photosynthetic apparatus of *Prochlorococcus* spp. is the chlorophyll *a/b* light harvesting antennae. The antenna proteins are made up of hydrophobic polypeptides of 31–38 kDa (Partensky et al., 1997), distinctly different from the much smaller 22–27 kDa polypeptides that form the light harvesting antennae (LHCII and LHCI) of algal and higher plants. The *Prochlorococcus* antenna proteins have molecular weights similar to those of *Prochloron didemnii* and *Prochlorothrix hollandica* (the other chlorophyll *a/b*-containing prokaryotes). Indeed, antibodies raised against LHCII crossreact to a wide range of heterologous LCHII proteins but do not recognize prokaryotic chlorophyll *a/b* antennae. Conversely, an antibody raised against the 33-kDa antenna polypeptide of *Prochlorothrix* crossreacts with the 30-kDa and 35-kDa antenna polypeptides in the same species as well as with those of *Prochloron* and *Prochlorococcus* (Bullerjahn et al., 1990; Bullerjahn and Post, 1993). As was described earlier for *Prochlorothrix* (Bullerjahn and Post, 1993; Post et al., 1993), *Prochlorococcus* showed a distinct energy coupling between chlorophyll *b* and PSI (Partensky et al., 1997). The antenna proteins are encoded by the *pcb* (prokaryote chlorophyll *b*) genes (LaRoche et al., 1996). These genes—together with the *isiA* gene which encodes a CP43'-like antenna under iron stress—have evolved from an ancestor closely related to the modern *psbC* gene encoding CP43, a PSII core antenna protein that binds chlorophyll *a* (LaRoche et al., 1996). The *pcb* genes have undergone a multiplication within the various *Prochlorococcus* ecotypes. The HL strain MED4 contains only one *pcb* gene, whereas the LL strains MIT9313 and SS120 contain 3 and 8 copies, respectively (Garczarek et al., 2000; Dufresne et al., 2003; Rocap et al., 2003). All copies of the *pcb* gene are nondifferentially expressed in these LL strains, albeit at very different steady state levels (Garczarek et al., 2001; Bibby et al., 2003).

The gene product of the sole *pcb* gene of *Prochlorococcus* MED4 forms an 18-mer antenna-protein ring that surrounds PS1 (Bibby et al., 2001b). This configuration is strongly reminiscent of the organization of IsiA antenna ring induced under Fe-stress in *Synechocystis* PCC6803 (Bibby et al., 2001a). The light harvesting antenna of *Prochlorococcus* MIT9313 is more extensive, and each photosystem has evolved with its own antenna composed of distinct proteins encoded by different *pcb* copies (Bibby et al., 2003). This is similar to the antenna partitioning in *Prochlorothrix hollandica*, where

the 30-kDa and 35-kDa chlorophyll *a/b* binding proteins are found to associate with PSI and a 33-kDa apoprotein co-purifies with PSI (Post et al., 1992). As for *Prochlorococcus* (Partensky et al., 1997), there was a distinct coupling between chlorophyll *b* and PSI in *Prochlorothrix hollandica* (Post et al., 1993). The unique partitioning of the chlorophyll *a/b* antennae in these phycobilisome-deficient oxyphotobacteria was first recognized for *Prochlorothrix hollandica* (Post and Bullerjahn, 1994b). The regulation of energy distribution in the latter involves the reversible phosphorylation of the 35-kDa antenna protein associated with PSI (Post and Bullerjahn, 1994), but this has yet to be elucidated for both the HL and LL *Prochlorococcus* spp.

As no heterotrophic capacity has been described for *Prochlorococcus* so far, the representatives of this genus appear to depend on photosynthetic activity, in support of an autotrophic lifestyle. The ambient light field that *Prochlorococcus* experiences, ranges in light intensity from 2000 µmol quanta·m^{-2}·s^{-1} (full sunlight at the sea surface) to more than four orders of magnitude less at the bottom of the photic zone. At these depths (>150 m) *Prochlorococcus* still maintains viable populations which experience a narrow spectrum centering around 490 nm (see, e.g., Veldhuis et al. [1993b], Lindell and Post [1995], Vaulot et al. [1995], and Partensky et al. [1999]). The success of *Prochlorococcus* at these depths is in part explained by the presence of divinyl chlorophyll *b* (which absorbs maximally at 488 nm; Goericke and Repeta, 1992) and the high absorption efficiency of its small cells (Morel et al., 1993). In addition to these properties, *Prochlorococcus* partitions the photic zone with HL- and LL-adapted ecotypes (Moore et al., 1998; West and Scanlan, 1999; West et al., 2001). Moreover, these ecotypes display plasticity in their pigment contents as judged from cellular fluorescence levels which increase with depth (Veldhuis and Kraay, 1990; Veldhuis and Kraay, 1993a; Veldhuis et al., 1993b). Adaptation in pigment contents was also found in culture studies of *Prochlorococcus* HL and LL strains (Partensky et al., 1993; Moore et al., 1995; Moore and Chisholm, 1999). Experiments of photosynthetic activity and growth concluded that HL *Prochlorococcus* organisms have a lower light utilization efficiency than their LL counterparts at low light intensities (though photosynthesis reaches maximal rates at higher light intensities) and are less sensitive to photoinhibition (Partensky et al., 1993; Moore et al., 1995; Moore and Chisholm, 1999). Similarly, growth rates of the HL strains peak at higher light intensities than those of the LL strains (Moore et al., 1995; Moore and Chisholm, 1999).

Nutrient Metabolism and Acquisition

Nitrogen

Little is known about the general features of *Prochlorococcus* metabolism, such as cell wall composition, carbon fixation, heterotrophy, carbon metabolism, etc. However, because *Prochlorococcus* are abundant in nutrient-depleted ocean waters, the nutrient metabolism of these organisms has received some attention in recent years. The major focus has been the ability of *Prochlorococcus* to scavenge different nitrogen (N) species and its ability to respond to N-stress. All *Prochlorococcus* strains studied are capable of ammonium acquisition, and some can utilize nitrite as the sole N-source (Moore et al., 2002). None of these *Prochlorococcus* strains is capable of N$_2$-fixation or of nitrate utilization (Moore et al., 2002). Whereas a N$_2$-fixation capacity is also absent from the closely related marine *Synechococcus*, virtually all strains of this genus are known for efficient utilization of nitrate (Moore et al., 2002). Most *Prochlorococcus* can use urea, with LL strain SS120 being a notable exception (Moore et al., 2002; Dufresne et al., 2003). No evidence has yet been found that *Prochlorococcus* uses externally supplied amino acids. Ammonium is a preferred N-source and the *amt* gene, encoding an ammonium permease, is abundantly expressed independently of the N-status of the cells (Lindell et al., 2002). A urease enzyme complex has been identified and characterized after purification (Palinska et al., 2000). In addition, genes encoding an ATP-binding cassette (ABC)-type transporter for urea were identified by similarity in the *Prochlorococcus* MED4 genome (Rocap et al., 2003). Since not all *Prochlorococcus* strains can utilize externally applied urea, this suggests that urease activity has a dual function in this genus: the acquisition of urea as a natural N-source and the removal of internally generated urea. Both ammonium and urea utilization are thought to satisfy most of the N-requirement, as they are N-sources which are readily regenerated in the surface layers of their ocean niche. Nitrite utilization is rarer and apparently limited to LL *Prochlorococcus*: strain MIT9313 was shown to carry *nirA* as well as *cysG*, which encode assimilatory nitrite reductase and sirohaem synthase, respectively (Rocap et al., 2003). Surprisingly, some *Prochlorococcus* strains have genes encoding a putative ABC-type transporter for cyanate as well as the gene for cyanate lyase, which opens the possibility for utilization of externally available cyanate (Rocap et al., 2003), which so far has not been identified as a natural N-source. Thus, all known N-sources are converted into ammonium and they are

assimilated via the glutamine synthetase-glutamate synthase (GS-GOGAT) pathway, as a glutamate dehydrogenase activity is lacking. GS was partially purified and characterized (El Alaoui et al., 2003), but GS protein levels and activity showed restricted, inconsistent change with various manipulations including changes in N-nutrition, inhibitor additions, and light and dark treatment (El Alaoui, 2001).

Like other cyanobacteria, *Prochlorococcus* can adapt to utilize different N-sources and respond to N-stress. Sensing and subsequently responding to changes in N- and C-fluxes constitute a major challenge to the cyanobacterial cell. As in other cyanobacteria, all *Prochlorococcus* strains studied so far contain P_{II} (the *glnB* gene product) and NtcA, both key players in N-stress responses (Lindell et al., 2002; Palinska et al., 2002; Dufresne et al., 2003; Rocap et al., 2003). The deduced amino acid sequence of *glnB* has distinct cyanobacterial motifs (Palinska et al., 2002), and *ntcA* sequences are highly similar to those of marine *Synechococcus* (Lindell et al., 2002). However, expression patterns suggest that the function of both genes is limited in *Prochlorococcus* PCC9511.

Phosphate

Prochlorococcus requires externally supplied phosphorus (P) in addition to combined nitrogen for sustained growth. The P-requirement of *Prochlorococcus* spp. is notably lower than that reported for other cyanobacteria (Bertilsson et al., 2003; Heldal et al., 2003). Whereas all *Prochlorococcus* spp. grow on phosphate as the sole P-source, some strains can also utilize organic P-sources, presumably aided by alkaline phosphatase activities (L. R. Moore, personal communication). Surprisingly, *Prochlorococcus* carries the genes for phosphonate uptake and utilization. Phosphonates are a utilizable P-source for marine *Synechococcus* spp. (Palenik et al., 2003). The genes encoding functions of phosphate uptake and P-stress responses have been identified. They include the genes for an ABC-type transporter and P-stress genes like *pstS* (which encodes a periplasmic substrate-binding protein with a high affinity for phosphate) and *psiP* (whose gene product has not been characterized; Scanlan and West, 2002). The adaptive response to P-stress in cyanobacteria is mediated via a histidine kinase *phoB* gene. A homologue of this gene has been identified in *Prochlorococcus* strains MED4, MIT9313 and SS120 (Scanlan and West, 2002; Mary and Vaulot, 2003). However, the *phoR* gene that encodes the response regulator PhoR was identified in strain MED4 but not in strain SS120. An apparently dysfunctional *phoR* gene was found in

strain MIT9313 (Scanlan and West, 2002; Mary and Vaulot, 2003). An additional gene, *ptrA* that encodes a putative transcriptional activator induced by P-stress, was also identified in *Prochlorococcus* (Scanlan et al., 1997; Scanlan and West, 2002). The P-stress response in *Prochlorococcus* is thus a complex matter that requires intensive further study. This is further strengthened by the observation that the phosphate availability in some marine water bodies, abundantly populated with *Prochlorococcus*, is cause to P-stress responses (Fuller et al., 2005) and growth arrest (Parpais et al., 1996) of these picocyanobacteria.

Iron and Trace Metals

Little is known about the requirements of *Prochlorococcus* for iron and trace metals. Iron (Fe) is an essential nutrient, and depth profiles of Fe-concentrations in the surface ocean often resemble those of the macronutrients, with depleted levels near the surface and accumulation at depths below the photic zone (Martin and Gordon, 1988). *Prochlorococcus* populations were found to be Fe-limited in the eastern equatorial Pacific (Mann and Chisholm, 2000). An Fe-induced transcriptional activator gene (*fur*) was identified in both the MED4 and MIT9313 strains (Rocap et al., 2003). Genes that are potentially controlled by Fur include *isiB* (flavodoxin), genes encoding Fe-storage in the form of ferritin, and an ABC-type iron transporter. Many of these genes have a putative Fur box motif in the promoter region. Typically, *Prochlorococcus* lacks the genes involved in the synthesis of Fe-complexation via siderophores (Rocap et al., 2003). Both *isiB* and one of the *pcb* genes are upregulated in strains MIT9313 and SS120 under Fe-stress (Bibby et al., 2003). Trace metal studies have shown a high sensitivity of *Prochlorococcus* to copper—LL strains more so than their HL counterparts—with toxicity becoming apparent at free Cu^{+2} concentrations of <10 pM (Mann et al., 2002). This sensitivity is greater by orders of magnitude than that found for marine *Synechococcus* and eukaryotic algae, and it may be a contributing factor in the global distribution of *Prochlorococcus* (Mann et al., 2002). *Prochlorococcus* has a specific requirement for the trace metal cobalt, needed in enzymes like carbonic anhydrase, which cannot be replaced by, e.g., zinc (Saito et al., 2002). Cobalt scavenging may involve ligands secreted by the *Prochlorococcus* cells, as cobalt uptake occurs at elevated rates in aged, conditioned medium as compared to uptake rates in fresh growth medium which permits uptake of Co^{+2} only (Saito et al., 2002).

Genomics

One of the exciting recent developments in the biology of *Prochlorococcus* is as a result of the wide attention this genus has received in genome sequencing projects. This interest was generated by the recognition that *Prochlorococcus* is one of the major primary producers in the sea and thus a major contributor to drawdown of atmospheric CO_2 into particulate organic matter. Over the last decade much attention has been paid to remedy elevated levels of CO_2 (and thus global warming) by increased marine productivity supported by large-scale fertilization of the surface ocean. Genome sequencing on the one hand provides in depth understanding of the gene pool underlying the global success of the ubiquitous unicellular cyanobacteria *Prochlorococcus* and the related *Synechococcus*. Three *Prochlorococcus* genomes, those of the strains MED4, MIT9313 and SS120, have been sequenced in full (Dufresne et al., 2003; Rocap et al., 2003). Additional genome sequencing for strains MIT9312 and NATL2A has been undertaken, but these sequences may be partial with an approximately 95% coverage. Although they are among the smallest genomes known, the genomes of different *Prochlorococcus* strains vary considerably in size (Table 2). As a result, the LL strain MIT9313 carries ca. 50% more genes than the HL strain MED4 (Rocap et al., 2003). Moreover, the MIT9313 is relatively rich in G+C as compared to MED4. However, another LL strain, SS120, is characterized with a genome size and G+C content more similar to that of MED4 than to the other LL strain MIT9313 (Dufresne et al., 2003). The genome of *Prochlorococcus* strain MED4 is so far the smallest genome known for a photosynthetic organism, and it is tempting to speculate that this genome size may be close to the size of the gene pool minimum needed by a free-living photosynthetic organism (Rocap et al., 2003). However, a comparison of the (predicted)

genes within the available *Prochlorococcus* genomes shows that *Synechococcus* spp. share a common core of about 1310 genes (Dufresne et al., 2003; Rocap et al., 2003). This finding suggests that these genes carry out essential cell functions, whereas the remaining 300–1000 genes encode proteins involved in cellular interactions with the environment. These observations have further contributed to the establishment of *Prochlorococcus* as a model organism in comparative and functional genomics studies.

The small genome size of *Prochlorococcus* spp. may have resulted from active genome condensation, which started in an ancestor probably resembling modern day marine *Synechococcus*. Comparison of *Prochlorococcus* genomes relative to that of *Synechococcus* shows that rapid degeneration of genes—obvious from frameshifts and other mutations—preceded the eventual omission of these genes from the genome (Hess et al., 2001; Scanlan and West, 2002; Rocap et al., 2003). An example of such a deletion event explains why *Prochlorococcus* spp. are incapable of nitrate utilization. Figure 1 shows the genome region responsible for nitrate assimilation in *Synechococcus* WH8102. These genes encode a nitrate permease, the nitrate and nitrite reductases, and all enzymes required for the synthesis of their molybdopterin and sirohaem cofactors. A deletion event has removed the nitrate utilization genes from the *Prochlorococcus* MIT9313 genome, but the nitrite utilization genes *nirA* and *cysG* were retained. The LL strain MIT9313, phylogenetically related to marine *Synechococcus* (Moore et al., 1998), is indeed capable of utilizing nitrite but not nitrate (Moore et al., 2002). An additional deletion event occurred in MED4 and may have happened during the evolution of these more recent HL types. As a result of this event, MED4 lost the *nirA* gene and thus nitrite reductase activity, whereas the *cysG* gene was retained, as cells still require sirohaem for sulfite reductase activity (a conserved function). The HL strains are all incapable of nitrate and nitrite utilization (Moore et al., 2002). Similar scenarios were used to explain the omission of, e.g., phycoerythrin synthesis and phosphate stress genes (Hess et al., 2001; Scanlan and West, 2002; Rocap et al., 2003). These deletion events no doubt laid the foundation for the establishment of *Prochlorococcus* ecotypes with very high similarity at the 16S rDNA level but very different physiological properties finely tuned to very different ocean niches. However, gene duplication and acquisition of foreign DNA through lateral gene transfer also contributed to development of successful ecotypes. The most striking example of gene duplication is the *isiA*-related *pcb* gene in LL type *Prochlorococcus*, which is found with two copies in MIT9313 and

Table 2. Basic properties of the whole genome sequences of *Prochlorococcus* strains MED4, SS120 and MIT9313.

Prochlorococcus strain	MED4	SS120	MIT9313
Genome size (bp)	1,657,990	1,751,080	2,410,873
G+C content (%)	30.8	36.4	50.7
Transfer RNAs (no.)	37	40	43
Gene models (no.)[a]	1716	1884	2275
Genes shared (no.)[b]	1314	1308	1358

Abbreviation: bp, base pairs.

[a]Gene models are the total number of predicted genes (known, conserved hypothetical, and hypothetical genes).

[b]Genes shared are the number of genes in each genome that have an ortholog in the other *Prochlorococcus* genomes and in marine *Synechococcus* WH8102 (Dufresne et al., 2003; Palenik et al., 2003; Rocap et al., 2003).
Fig. 1. A comparison of nitrate and nitrite assimilation gene arrangements in a genomic region in *Synechococcus* WH8102 which contains further N-acquisition genes, as compared to similar genomic regions in the LL strain *Prochlorococcus* MIT9313 and the HL strain *Prochlorococcus* MED4. The *ppK*/*sigB* genes and *pyrG* (not shown) were chosen as marker genes indicating the flanking regions of the genomic regions. The genes indicated by the deletion events were lost from the genome and not translocated to other regions. Coding regions of known and putative genes are as represented. Black arrows indicate the direction of transcription, green arrows indicate genes involved in the assimilation of nitrate, pink arrows indicate genes involved in nitrite assimilation, and dark-blue arrows indicate genes needed for urea utilization. Known gene names are given above and open reading frame numbers (SYNWxxx) below the black arrows.

eight copies in strain SS120 (Garczarek et al., 2000; Bibby et al., 2003; Rocap et al., 2003). The expression of multiple *pcb* genes (Garczarek et al., 2001) provides the structural basis for different light harvesting antennae associated with each photosystem (Bibby et al., 2003) and for unusually high chlorophyll *b*/*a* ratios in these *Prochlorococcus* organisms (Moore et al., 1998; Moore and Chisholm, 1999). The expression of multiple *pcb* genes is thought to explain the success of LL *Prochlorococcus* types at depths where light is <0.1% of incident light at the surface. The genomic section between *mutS* and *gyrB* genes has been well conserved among marine *Synechococcus* and *Prochlorococcus*. However, the MIT9313 genome carries an uncharacteristic insertion of 33 genes—most encoding functions in lipopolysaccharide biosynthesis—which have a very different G+C content from that of the neighboring genome sections. Acquisition of this gene cluster in lateral gene transfer has been hypothesized (Rocap et al., 2003). Similarly, the genes involved in inorganic carbon acquisition are similar to those of the gamma-proteobacterium *Acidithiobacillus fer-*

roxidans rather than to typical cyanobacterial-type genes, again suggesting a lateral transfer of foreign DNA to the *Prochlorococcus* genome (Rocap et al., 2003).

The whole genome sequences available have altered our previous view of *Prochlorococcus* as a coherent genus specialized to meet the extreme environmental conditions imposed by stratified subtropical and tropical ocean. This view has changed to one of a genus displaying an enormous versatility in G+C content, codon usage, gene pool and gene expression for individual species or ecotypes, in which very few if any "luxury" genes are present. These are thereby optimally equipped to successfully invade and dominate in virtually every niche created by the steep and inverse gradients of light and nutrients in the ocean's photic zone.
